Fig. 1 SNPs, haplotypes and tag SNPs. (a) SNPs. Shown is a short stretch of DNA from four versions of the same chromosome region in different people. Most of the DNA sequence is identical in these chromosomes, but three bases are shown where variation occurs. Each SNP has two possible alleles; the first SNP in panel a has the alleles C and T. (b) Haplotypes. A haplotype is made up of a particular combination of alleles at nearby SNPs. Shown here are the observed genotypes for 20 SNPs that extend across 6,000 bases of DNA. Only the variable bases are shown, including the three SNPs that are shown in panel a. For this region, most of the chromosomes in a population survey turn out to have haplotypes 1–4. (c) Tag SNPs. Genotyping just the three tag SNPs out of the 20 SNPs is sufficient to identify these four haplotypes uniquely. For instance, if a particular chromosome has the pattern A-T-C at these three tag SNPs, this pattern matches the pattern determined for haplotype 1. Note that many chromosomes carry the common haplotypes in the population.

linkage disequilibrium between nearby SNPs in the human genome. Because of the strong associations between SNPs in a region, it is possible to use only a few carefully chosen SNPs to identify each of the common haplotypes in a region (Fig. 1c). Recent molecular surveys suggest that the human genome contains many discrete haplotype blocks that are sites of closely located SNPs.^[48] Each block may have a few common haplotypes that account for a large proportion of chromosomal variation. Between adjacent blocks are there large regions, called hotspots, in which recombination events occur with high frequencies. Several algorithms have been developed to identify a minimal subset of SNPs, i.e., “tagging” SNPs, that can characterize the most common haplotypes. The number and type of tagging SNPs within each haplotype block can be assumed to have determined prior to association studies.

QUANTITATIVE TRAIT NUCLEOTIDES

A haplotype represents a linear arrangement of nucleotides (alleles) at different SNPs on a single chromosome or part of a chromosome. The pair of haplotypes is called a diplotype. The observed phenotype of a diplotype is called a genotype. A diplotype is always constructed by two haplotypes, one from the maternal parent and the other from the paternal parent. Suppose there are two different SNPs on the same genomic region, one with two alleles *A* and *a* and the other with two alleles *B* and *b*, respectively. Allele *A* from SNP 1 and allele *B* from SNP 2 are located on the first homologous chromosome, whereas allele *a* from SNP 1 and allele *b* from SNP 2 located on the second homologous chromosome. Thus, *AB* is one haplotype and *ab* is a second haplotype, and both constitute a diplotype *ABlab*.

In a practical genetic analysis, we can only observe the genotype expressed as *AaBb*. However, the double heterozygote may be one (and only one) of two possible diplotypes *ABlab* and *AblaB*. But these two diplotypes cannot be directly observed and should be inferred from SNP genotype data. In practice, it is important to estimate haplotype effects on a quantitative trait based on the diplotypes and therefore genotypes. For example, if an animal carries haplotype *AB*, it will grow better than other animals that carry any other haplotypes, *Ab*, *aB* and *ab*. For this reason, the same genotype *AaBb* may perform differently, depending on what diplotype it carries. If this genotype is diplotype *ABlab*, then it will have a better growth. If the animal is diplotype *AblaB*, its growth will be poorer. The statistical model being developed will be used to determine which diplotype is associated with better growth in experimental crosses.

Genetic mapping with the diplotypes has power to detect particular DNA sequences that encode a complex trait. The nucleotide components of a haplotype or diplotype that affect a quantitative trait are called quantitative trait nucleotides (QTNs). As mentioned above,

the human genome project generates massive amounts of DNA sequence data across the human genome^[49] and this will facilitate the complete identification of QTNs responsible for complex traits, their number and distribution as well as the number and order of nucleotides that comprise the QTNs. Also, the frequencies of haplotypes for a QTN are also important for the understanding of the population structure and diversity.

As a series of DNA sequences, a QTN that encode a particular trait can be detected with SNPs genotyped from candidate genes or throughout the whole genome. The recent development of the human haplotype map (HapMap) has made it possible to detect genome-wide QTNs that are responsible for complex diseases.^[49] Liu et al.^[50] were among the first who proposed a general statistical model for the characterization of QTN variants that encode a complex phenotype in a natural population. A strategy based on QTL information has also been developed to identify QTNs for complex traits in controlled crosses.^[51]

GENETIC MAPPING BY INCORPORATING MECHANISTIC PATHWAYS

Traditional genetic-mapping approaches are based on a direct relationship between genotype and phenotype through statistics. Functional mapping relates DNA variants with phenotypic traits at different stages of development via mathematical models. All these connections are based on a simple genotype-phenotype correspondence. Given that a black box is not revealed from the genotype to phenotype, they are not able to unravel the mechanistic and regulatory process of how genes control a phenotype. Despite continuous addendums and modifications received in the recent past, the “Central Dogma” of biology, **DNA → mRNA → enzyme (inactive) → enzyme (active) → metabolite(s) → metabolism → cellular physiology → life**, is still thought to be a fundamental rule to form, control and direct every aspect of a living system (Fig. 2). Regulatory control is exerted to affect virtually all these levels.

These pathways and processes from DNA to life can be viewed as a biological system comprised of large populations of elements that function together within the system according to unique design principles. Thus, the life can be defined by the structure and dynamics of the system. These two aspects, structure and dynamics, provide a baseline that can be used to analyze an essential property of the biological system: robustness, i.e., single perturbations will rarely cause systemic failure.^[52,53] In such a biological system, different parts are assembled together, and they interact with each other and with the surrounding environment by two main types of digital information: genes, which encode the proteins through the intermediary of RNA, and regulatory networks, which specify how these genes

Fig. 2 Biological networks of the phenotypic formation and development of a trait. Genetic mapping is moving from a direct genotype-phenotype correspondence to regulatory networks that underlies the formation of a phenotypic trait

are expressed in time and space. Genetic information can operate across such different time spans: Millions to tens of years (evolution and conservation of species), tens of years to hours (life cycles), and weeks to milliseconds (physiology),^[54] whereas biological information operates on multiple levels of organization (molecular, cellular, tissular, organic, systemic, etc.) in complex networks.^[53]

Current biotechnologies can measure gene expression, a process by which inheritable information from the DNA sequence is converted into a functional gene product (such as RNA or protein). Aimed to gain an insight into the entire genome of an organism, genomics is the study of the whole set of genes of a biological system. Likewise, the object of the study of proteomics is the proteome, understood as the entire collection of proteins that are expressed in a system. In this way, the respective discipline arises from the study of the transcriptome (the set of RNA transcripts of a specific system) and the metabolome (the entire range of metabolites taking part in a biological process). Other omes (sets) that may also be of interest include: the interactome (complete set of interactions between proteins or between these and other molecules), the localizome (localization of transcripts, proteins, etc.), or even the phenome (complete set of phenotypes) of a given organism.^[52,55]

It is recognized that transcriptional, proteomic, and metabolomic expressions can be controlled by specific QTLs. Traditional genetic-mapping approaches can be used to map these QTLs, called eQTLs, pQTLs, and mQTLs, respectively, by viewing transcriptional, proteomic, and metabolomic data as general phenotypes. There is an increasing wealth of literature on the development of statistical models for mapping eQTLs, pQTLs, and mQTLs.^[56] Meanwhile, an increasing wealth of literature evidence has reported on the existence of these different types of QTLs.^[57] It is expected that genetic mapping can be more efficient and more biologically motivated when it is moved from a simple genotype-phenotype correspondence to the underlying regulatory network of trait formation (Fig. 2).

FUTURE DIRECTION: MODELING REGULATORY NETWORK

The information of omes enables scientists to measure multiple features of complex systems at various levels of biological organization from the cell to the whole organism within a defined, fully delineated framework. The challenge is therefore how this information is decoded according to the physiological function of the system studied.^[58]

To measure a system, even at the single-cell level, an understanding of how gene, protein, metabolic, and physiological events are expressed in time course is crucial. Attempts to correlate gene expression data with proteomic and metabolomic data have been made by using classic correlation methods or multivariate statistics. However, they have often proved to be unsatisfactory even for simple systems such as yeasts^[59] in large part because the timescales of various biological control functions are either very different or simply unknown. Fig. 3 shows such a problem in which two pairs of gene-protein couples are expressed in time course. It can be seen that the levels of mRNA transcripts are not consistent with protein levels on timescales.^[58] If the action of the stimulus, such as drug intervention, is at the genetic level, it will take a finite amount of time in a cell for the associated protein synthesis (or post-translational modification) to occur. Also, the duration of the gene events (t_g) and protein events (t_p) may be very different. All this will lead to the consequence that the observed covariance of the gene and protein events is highly dependent on sampling time point and frequency. As shown in Fig. 3, in some instances, a single sampling point (say τ_3) might result in the incorrect assumption that gene 2 co-varied with protein 1. The times of maximal activity or expression for protein may not be constant; for example, the t_p values and related turnover times are larger for protein 2 than protein 1.

A problem also exists when one attempts to correlate proteomic with metabolomic data. Currently, proteomic

Fig. 3 Time courses for two hypothetical gene–protein couples (relating transcription activity to protein level) that are up-regulated following a system stimulus, such as a drug intervention at time zero. Key: $g1(0)$, $p1(0)$ etc. describe the relative condition with respect to up regulation of each gene and protein at a given time-point (e.g. τ_1 , τ_2 , etc.), where (0) indicates baseline level and ($\uparrow$) indicates upregulation. Thus the post intervention observation of relative state can be seen to be dependent on sampling time-point. (Adapted from Ref. [58].)

data sets contain no information on the activity of specific proteins, which is dependent on their location in the cell and the presence of co-factors or inhibitors.

To understand the true quantitative relationship between the variation in activity of every one of the thousands of gene-protein couples or protein-metabolite couples in a cellular system, it is important to consider several critical factors, that is, the time displacement of the genetic and protein synthetic and post-translational events, their different timescales and their half-lives. Ordinary differential equations (ODE) that model electronic networks in engineering have been proposed to describe regulatory networks of a biological system.^[60–65] These ODE methods were applied to model the regulatory network of *Halobacterium salinarum*, suggesting that the model could predict mRNA levels of 2,000 out of a total 2,400 genes found in the genome (a network with 1,431 predicted regulatory influences controlling 459 biclusters that represent 85% of the genes in the genome).^[66] A similar application was made to model human regulatory networks (mediating TLR-5-mediated stimulation of macrophages) and several other microbial networks.^[63] The accuracy and precision of a regulatory network can be increased when the model is combined with environmental and genetic perturbations by incorporating the principle of functional mapping.

Statistical Principles for Clinical Trials

Allan Phillips

Wythe Research, Berkshire, U.K.

Abstract

This entry will focus on the key statistical principles of concern to regulators as identified in the most recent guidelines—namely, bias and robustness.

INTRODUCTION

The application of biostatistics in the drug development process is now recognized worldwide as being essential. Over the last 10–20 years, the increasing importance of biostatistical methodology has led to a rapid increase in the biostatistical resources involved in drug development, especially in the pharmaceutical industry in Europe, the United States, Japan, and elsewhere.

Before regulatory agencies approve a new drug, they require substantial evidence of effectiveness and safety through clinical trials. However, before it can be tested in humans, a number of animal studies need to be conducted to assess the pharmacological characteristics, efficacy, and safety of the drug in animals. To assist researchers in fulfilling the requirements, guidelines have been developed for the various stages of the development process, including Good Laboratory Practice (GLP), Good Clinical Practice (GCP), and Good Regulatory Practice (GRP). As discussed by Chow,^[1] adherence to these guidelines relies heavily upon the implementation of Good Statistical Practice (GSP). In essence, this demands that:

- a. The scientific or medical questions under investigation are addressed using a valid design.
- b. Representative samples are drawn at random for testing.
- c. Statistical inferences are based on appropriate statistical methods and provide an unbiased assessment.

One of the key stages of the drug development process is the clinical development phase, where the goal is to establish evidence of effectiveness in humans through clinical trials. Statistical principles are now commonly used in such trials to assist researchers in providing a more accurate and reliable assessment of any treatment effect.

KEY STATISTICAL PRINCIPLES

Most of the key statistical principles for clinical trials relate to minimizing bias and to ensuring the robustness of conclusions drawn from the data. As defined in the

International Conference on Harmonization (ICH) guideline E9 on “Statistical Principles for Clinical Trials,”^[2] bias is the systematic tendency of any factor associated with the design, conduct, analysis, and interpretation of the results of clinical trials to make the estimate of a treatment effect deviate from its true value. In clinical trials, there are usually two types of bias that are of concern—statistical bias and operational bias. Bias introduced during the conduct of a clinical trial is often referred to as “operational” bias. The other sources of bias are referred to as “statistical” bias. Because bias cannot be measured or even quantified, it is often impossible to adjust for it in the statistical analysis. Thus it is imperative that when designing a clinical trial, all potential sources of bias are identified and, wherever practical, eliminated. The presence of bias can seriously compromise the credibility of a clinical trial, including any inference that is made from a trial.

In many statistical textbooks, robustness relates to the vulnerability of a statistic to the presence of outliers and dirty data. A robust statistic is one that works well for a wide variety of population types from which the samples are drawn. In the clinical trial context, however, robustness relates to the reliability of the inference drawn from the clinical trial data. Because it is unlikely that all sources of bias can be identified and eliminated, it is important to show that the results are unaffected by any limitations of the data, assumptions, and analytical techniques used. Conclusions of a clinical trial that are not substantially affected when alternative approaches are employed are said to be robust.

Two other statistical principles for clinical trials, although less well recognized in the published literature, are measurement error and efficiency. Measurement error relates to the need for any measurement taken on a patient to be precise and reproducible so that observer differences do not bias treatment comparisons. Efficiency relates to the desire to not only provide an unbiased estimate of a treatment effect, but to use the estimator that has minimum error associated with it.

After a brief look at the regulatory guidelines relating to statistical principles for clinical trials, this entry will focus

on the key statistical principles of concern to regulators as identified in the most recent guidelines—namely, bias and robustness. Potential sources of bias in study design and analysis will be reviewed. Advice will be provided on how to minimize the impact of any bias on inferences to be drawn from clinical trials, especially during study design. Because bias can occur in subtle and unknown ways, it can never be totally eliminated. Thus the need to investigate the robustness of principal inferences will also be considered.

REGULATORY REQUIREMENTS

In 1988, the U.S. Food and Drug Administration (FDA) issued a guideline entitled “Guideline for the Format and Content of the Clinical and Statistical Sections of New Drug Applications.”^[3] The purpose of the guideline was to provide direction to sponsors in the design, conduct, analysis, and evaluation of clinical trials. The guideline proved historic in that it was the first regulatory document to describe some of the fundamental statistical principles for clinical trials.

Since 1988, other regulatory authorities have issued guidelines partially or entirely concerned with statistical principles for clinical trials. The most recent and most important biostatistical regulatory guideline is the ICH guideline E9 on “Statistical Principles for Clinical Trials.” An ICH expert working group developed the guideline. The group utilized the Committee for Proprietary Medicinal Products (CPMP) biostatistical guideline^[4] as a starting point, but was also influenced by guidelines from the U.S. Food and Drug Administration^[3] and the Japanese Ministry of Health and Welfare^[5] guideline. The guideline was adopted by the CPMP at its March 1998 meeting and is therefore now operational in Europe. It has also been adopted in United States and Japan. The importance of this guideline is best illustrated by the number of times it has been referenced in other articles within this encyclopedia.

More detailed guidance on the statistical principles relating to selected topics discussed in ICH E9 “Statistical Principles for Clinical Trials” has been issued in recent years by the CPMP in the form of “Points to Consider” documents. They include, for example, Switching Between Superiority and Non-Inferiority,^[6] Meta Analysis and One Pivotal Study,^[7] and Missing Data.^[8] Others are planned to be issued in the future.

STATISTICAL DESIGN

The main source of bias in study design usually arises from the allocation of treatments to patients. However, a variety of statistical techniques such as blinding, randomization, stratification, and minimization can often minimize bias.

Blinding

Pocock^[9] points out that in any clinical trial, the comparison of treatments may be distorted if the patient and those responsible for treatment and evaluation know which treatment is being used. Consequently, to limit the occurrence of conscious and unconscious bias arising from knowing which patients are assigned to which treatment, wherever possible, patients, clinicians, and evaluators should be blinded to treatment assignments. When this is achieved, the trial is known as a double-blind clinical trial.

Blinding also helps to ensure that investigators do not influence the randomization of patients to treatments. Doing so has the clear potential for introducing bias and clearly violates the statistical benefits of randomization, which is discussed next.

Although double-blind trials are the optimal design, they are usually only feasible when comparing treatments of a similar nature. The suitable use of matching placebos in some trials is helpful to make treatments indistinguishable. However, in some clinical trials, it is not possible to have identical treatments (e.g., consider an oncology trial to compare chemotherapy vs. surgery). Consequently, other types of design, such as open-label trials and single blind trials, are employed. Further details can be found in ICH E9 or in other entries in this encyclopedia. In all cases, the essential aim of “blinding” is to prevent the identification of treatments until such opportunities for bias have passed.

Randomization

Randomization helps to avoid possible bias in the selection and the allocation of subjects arising from the predictability of treatment assignments. It introduces a deliberate element of chance into the assignment process. In the simplest of trials, a statistician prepares a randomization list. The list is used to make up identical packages containing the different treatments to be studied in the clinical trial. Patients are then sequentially assigned to the next unidentifiable package on the randomization list. This later part of the process is either manually performed by the investigator at the study site, or, more commonly now, via telecommunication systems or computer software packages.

To improve the comparability of the treatment groups, patients are sometimes randomized in blocks or strata. This is especially helpful when the patient characteristics change over time (e.g., as a result of changes in recruitment policy). Another example where it is helpful to block is when environmental conditions may vary over time such as in an allergy study over several seasons. Most multicenter trials have a separate block or stratum for each center. Stratification by important prognostic factors measured at baseline (e.g., age, sex) may also be valuable at times in order to help achieve balanced treatment groups.

An alternative technique used in clinical trials to minimize bias in the allocation of treatments to patients is minimization. The technique involves the dynamic allocation of patients to treatments. A patient is allocated to a treatment based on the demographic characteristics of the given patient and of those already assigned to treatment. In a stratified trial, the allocation balances within the stratum to which the patient belongs.

Further details on randomization, stratification, and minimization to avoid selection and allocation bias can be found in ICH E9 or in other entries in this encyclopedia.

STATISTICAL ANALYSIS

There are many potential sources of bias that can occur while analyzing clinical trial data. Some of the more important and frequently occurring sources include the following:

1. Exclusion of patients from the analysis based upon the knowledge of the treatment that they received and their outcome.
2. Missing data.
3. Outliers.
4. Improperly conducted interim analyses.

Although statistical methods that minimize the potential impact of any bias are available, in reality, bias will always occur to some extent. Subsequently, it is important that inferences drawn from a clinical trial are robust.

Analysis Sets

The ICH E9 guideline makes it clear that regulatory statisticians are concerned about bias introduced as a result of excluding patients from analyses based upon the knowledge of the treatment that patients received and their outcome. To overcome this, in general, it is advisable to demonstrate a robustness of the principal clinical trial results to alternative choices of the set of patients analyzed, defined prior to unblinding a study.

Depending on the disease and context, it is valid to omit patients from an analysis, especially when the approach is specified in advance in the protocol. A number of reasons used include the following:

- a. Failure to take even one dose of medication.
- b. Absence of disease (e.g., oncology–nonmeasurable lesion, antibiotics–no bacteria detected).
- c. Fraudulent data from a center.
- d. Center measuring primary outcome incorrectly.

If patients are to be omitted from an analysis, then it is important to clearly document the reasons why. This is needed for regulators and others to be able to explore any

potential bias arising from the exclusion of the patients. If the number of excluded patients is substantial, then a sensitivity analysis should always be conducted. This is achieved via the use of different analysis populations such as the full analysis set, per protocol analysis set, etc. Further details are provided in the ICH E9 guideline.

As discussed earlier, randomization helps to avoid possible bias in the selection and the allocation of subjects arising from the predictability of treatment assignments. In some trials, patients can fail to take the randomized treatment but receive one of the other clinical trial treatments, which is another potential source of bias. As pointed out in Phillips et al.,^[10] in nearly all clinical trials, safety data should be analyzed according to the treatment actually taken. For efficacy analyses, however, the approach probably depends on how and why the subjects were misallocated. In situations where the misallocation may cause bias, the analysis should be conducted according to the original randomization (e.g., in open trials where patients may be allocated to surgical intervention).

Missing Data

A potential source of bias when analyzing clinical trial data is the missing data. Every effort needs to be directed toward ensuring that patients comply with the protocol concerning the collection and the management of data to minimize the problem. However, in reality, missing data are likely to always occur. This can be for a variety of reasons including, for example, patient refusal to participate in a clinical trial (e.g., withdrawal of consent, etc.), patient experiencing a treatment-related event (e.g., a treatment success, failure, or an adverse reaction), patient failure to attend a visit (e.g., missed appointment on vacation), or one of many other reasons.

As stated in the Committee for Proprietary Medicinal Products Points to Consider Document on Missing Data,^[8] bias arising from missing data may affect the estimate of a treatment effect, the comparability of the treatment groups, and the representativeness of the clinical trial sample in relation to the target population. The extent of the bias depends on many factors (e.g., the risk of bias in the estimation of a treatment effect depends upon the relationship among the true value of the missing data, the treatment, and the outcome). It is likely that an estimate of a treatment effect will be biased when a poor outcome is more likely to be missing in one treatment group because it is not as effective.

No universally accepted methods exist for handling missing data. In fact, a number of methods employed by statisticians to address the issue of bias arising from missing data in themselves provide a source of bias. For example, a technique frequently used in the pharmaceutical industry is to carry forward the last value observed for a patient for all other assessments if a patient discontinues a clinical trial. This, in itself, may introduce bias in that a

treatment effect is likely to be overestimated if the missing value relates to the treatment and the true value of the missing data (e.g., one treatment does not provide as rapid a response as another and a poor outcome is more likely to be missing). Subsequently, it is imperative that an investigation of the robustness of the principal inferences to be drawn from a clinical trial is explored using different data assumptions concerning any missing data.

Outliers

One of the main statistical principles for clinical trials relates to ensuring that inferences drawn from clinical trial data are robust. That is, there is a need to establish that results are unaffected by any limitations of the data, assumptions, and analytical techniques used. Subsequently, the influence of outliers or extreme values on inferences needs to be carefully investigated. As discussed in ICH E9, procedures for identifying both statistical and medical outliers, and how they will be handled in the statistical analysis, need to be defined prior to unblinding a clinical trial. The procedures should be such as not to favor one treatment or another; otherwise, the estimated treatment effect would be biased. As pointed out by Gardner and Altman,^[11] because outliers often have a pronounced effect, it is common to analyze the data both with and without such observations to assess how much any conclusion depends on these values.

Interim Analyses

An interim analysis of accumulating data in a clinical trial, either formally or informally, is an established practice for ethical and scientific reasons. However, a major concern to regulators and others involved in the design and conduct of clinical trials is the introduction of bias following an interim analysis. Any interim analysis that is not planned appropriately (with or without the consequence of stopping the trial early) may flaw the results of a trial and possibly weaken confidence in the conclusions drawn.

Broadly speaking, methodology exists to address statistical bias arising from interim analyses. Significance tests are usually corrected properly for the interim looks; however, treatment effect estimates are not (e.g., see Facey and Whitehead^[12]). End points correlated with the interim analysis end point are also not adjusted.

To minimize operational bias, Data Monitoring Committees are often used to assess the progress of a clinical trial, safety data, and critical efficacy data at specific time points, particularly multinational, multicenter trials. As discussed by Armitage,^[13] Data Monitoring Committees come in many forms. There is no standard formula suitable for all clinical trials. Each Data Monitoring Committee has to work out its own *modus operandi*. Nevertheless, the practices and experiences of various committees have been documented and provide useful guidance.

For some clinical trials, Data Monitoring Committees comprise solely of representatives from the sponsor organizations (i.e., people with a vested interest in the results of the trial). Better control may be demonstrated when an external monitoring committee is used. By establishing an independent external group, it is possible to protect the integrity of the trial from adverse impact resulting from access to trial information. However, whether an internal or external monitoring board is used, documentation is essential and needs to be available to regulators (roles and responsibilities, minutes, etc.).

The PMA Biostatistics and Medical Ad Hoc Committee has published a more comprehensive discussion on interim analyses in "Interim Analysis in Pharmaceutical Industry."^[14]

CONCLUSION

The application of biostatistics in clinical trial design and analysis is now recognized worldwide as being essential. Many of the key statistical principles attributed to statisticians in clinical trial design and analysis relate to minimizing bias and to ensuring robustness of conclusions drawn from the data. Because bias cannot be measured or even quantified, it is imperative that when designing a clinical trial, all potential sources are identified and, wherever practical, eliminated. Failure to do this can seriously affect the credibility of a clinical trial including any inferences that are drawn from the data. In addition, it is important that inferences drawn from clinical trials are shown to be robust. A more detailed discussion of the topics covered in this entry and other related issues can be found in the ICH E9 guideline entitled "Statistical Principles for Clinical Trials."

Statistical Process Control

William R. Myers and William A. Brenneman

The Procter & Gamble Co., Mason, Ohio, U.S.A.

Abstract

Statistical process control (SPC) is a collection of tools and techniques used to monitor, to control, and to improve a process. This entry discusses the details of statistical process control, including several examples of process flowcharts, control charts, and cause-and-effect diagrams to illustrate this concept.

Keywords: Charts; Histograms; Statistical process control.

INTRODUCTION

Statistical process control (SPC) is a collection of tools and techniques used to monitor, to control, and to improve a process. The primary goal of SPC is to achieve process stability and to improve process capability by reducing variability. A process is defined as being in *statistical control* when only a certain amount of natural or routine variability exists. This variability is intrinsic to the actual process and cannot be fully eliminated. On the other hand, a process may be exposed to sources of variation that are beyond the natural variability of the process. These sources of variation are defined as *assignable or special causes*. A process where assignable causes exist is defined as being out of control (or not in statistical control). A process that is not in a state of statistical control is one in which the variable that is being measured does not have a stable distribution. A few examples of assignable causes are nonconforming raw material, operator error, analytical error, and machine malfunction. A primary goal of SPC is to detect, as swiftly as possible, any assignable causes so that a proper investigation can take place in order to fix the problem. The ultimate objective of SPC is the elimination of variation in the process as a result of assignable or special causes.

Quality control and, more specifically, SPC have become a critical component within the pharmaceutical industry. Both batch release criteria—such as assay content uniformity and dissolution, as well as process control testing like tablet weight, hardness, and gauge—can be effectively monitored through SPC. The need for efficient and stable processes with improved capability within a highly regulated environment has made SPC an essential component within a pharmaceutical company's quality organization. Some results of poor process quality could include an excessive scrapping of entire lots and unnecessary costs and time to perform rework on poor quality product.

OVERVIEW

The potential success of a complete SPC program requires management involvement and the commitment to the quality improvement process throughout the organization. It must be clearly pointed out that SPC should not only be applied when trouble occurs and subsequently abandoned, but should be applied throughout the life of the process. Quality improvement should become a part of the culture and should be a proactive tool rather than a reactive tool.

The most important and broadly used tools in SPC are

1. Histograms.
2. Pareto charts.
3. Cause-and-effect diagram.
4. Flowchart.
5. Control chart.

Histograms

A histogram is a graphical representation of the frequency distribution of a continuous variable. Fig. 1 illustrates a histogram of tablet weight data. Histograms allow one to more easily observe the shape, location, and spread of the data. Histograms will point out skewness and heaviness in the tails, and may also give an indication of outliers. From Fig. 1, it is clear that the tablet weight has an approximate normal distribution, with an approximate location (mean) of 10 and a range of 1.5. The following are some general guidelines for constructing histograms:

- Select the number of bins (or groups) approximately equal to the square root of the sample size.
- The width of the bins should be uniform.
- Start the lower limit for the first bin just below the smallest data point.

Fig. 1 A histogram of tablet weight (mg)

Histograms can also be used to evaluate process capability, by plotting the histogram along with the specification limits in order to show the portion of data that exceeds the specification limits. Furthermore, superimposing the best-fitting normal curve on the histogram provides a graphical way to check for normality and, if specification limits are plotted, will also graphically show the theoretical out-of-specification probability. Montgomery^[1] states that at least 100 or more observations should be used in order for the histogram to be moderately stable.

Pareto Charts

The Pareto chart (or diagram) is a frequency distribution of attribute data arranged by category (i.e., bar chart). A Pareto chart can determine those problems that occur most frequently and thus allows the efforts and resources to be focused on those particular concerns. However, the chart does not directly differentiate the severity of the problems. Fig. 2 is an example of a Pareto chart based on hypothetical data. In the example, 60% of problems found were related to cracked tablets; 20% were related to broken tablets; 10% were related to non-uniform tablet size, shape,

Fig. 2 An example of a Pareto chart

or color; 5% were related to uneven tablet coating; and 5% were related to other factors. Before starting to work on the cracked tablets, an analysis would need to be done to see whether fixing the cracked tablets would be more beneficial to the business than fixing the broken tablet problem. See Gopal^[2] for another example of a Pareto chart.

Cause-and-Effect Diagram

The cause-and-effect (or fishbone) diagram is a powerful tool used to determine the potential causes of undesirable (or desirable) results. After a problem has been identified, a team should be created to brainstorm on major potential cause categories of the undesirable effect. Some examples of major potential cause categories are raw materials, machines, analytical methods, and personnel. Next, possible causes within each major potential cause categories are identified and rank-ordered in terms of most likely to cause the undesirable result. A template for a cause-and-effect diagram is provided in Fig. 3. One critical outcome of such an exercise is to identify all possible causes of the problem and thus remove the personal bias individual team members have to dismiss causes they believe to be implausible. Another outcome is that the cause-and-effect diagram can be used by the team to monitor their progress in solving the problem by adding and by deleting possible causes along the way.

Process Flowchart

A process flowchart is a chronological sequence of process steps. They are very useful in visualizing and defining the process in order to better understand and to improve the process. Process flowcharts should include enough detail to be used as an effective resource when a problem occurs, or when an improvement effort begins but should not be so detailed as to cloud the overall picture. Process flowcharts are invaluable when new members are added to a team and need to learn quickly the main features of the manufacturing process. Process flowcharts can also aid in the brainstorming sessions that lead to the construction of

Fig. 3 A template of a cause-and-effect diagram

cause-and-effect diagrams. An example of a basic flowchart is given in Fig. 4, where the potential main components of a pharmaceutical process are graphed.

Control Charts

The control chart is the most widely used tool within the SPC tool bag. A control chart is used to detect the out-of-control state of a process. As previously stated, it is important that the process shift be detected quickly so that the problem can be corrected before many non-conforming (or out of specification) products are produced. The proper use of a control chart can often prevent an overreaction to changes that represent only random fluctuation. An example of a control chart ($\bar{X}$ chart) is presented in Fig. 5, where each point on the plot represents a sample average of a quality characteristic (tablet weight) taken over time. The sample values are divided into subgroups, which are often called rational subgroups. The rational subgroups are chosen so that the within-subgroup variability is small and the between-subgroup variability is maximized so that if assignable causes are present, they can be detected with high probability. The time order of production is a natural way to select subgroups. The control chart has a centerline that corresponds to the grand average of the quality measurement. The other two lines represent the lower control limit (LCL) and the upper control limit (UCL), which are constructed in such a way that if a sample point falls outside the limits, it is evidence that the process is out of statistical control.

In most cases, 3σ control limits are used in order to maintain a small probability of a sample point falling outside the control limits given that the process is in control (i.e., *false alarm* rate). If the variable is normally distributed and 3σ control limits are used, the probability is 0.0027 that the sample point (e.g., mean for the $\bar{X}$ chart) falls outside the control limits, given that the process is in control. It has become general practice to use 3σ control limits, even if the distribution of the quality characteristic is not normally distributed. One common misconception is that data must be normally distributed in order to be placed on a control chart. However, Burr^[3] and Schilling and Nelson^[4] have demonstrated that a control chart, with 3σ control limits, is reasonably robust to the normality assumption. With respect to an $\bar{X}$ chart, even if the individual values are not normally distributed, the distribution of $\bar{X}$ is approximately normal and thus there is fairly accurate control over the probability of a type I error for the case in which σ is known. It has been demonstrated over the many years of using the control chart that the 3σ control limits do very well in practice.

Fig. 4 The main components of a pharmaceutical flow chart

Fig. 5 An example of an $\bar{X}$ chart for tablet weight

Preliminary or trial control limits must be determined in order to evaluate the future output of a process. The control limits should be based on data that are in statistical control. The standard practice is to use at least 20 subgroups in order to compute the preliminary control limits. The sample size within each sample is typically small (e.g., three to eight). If the sample statistic (e.g., $\bar{X}$) for each sample is inside the control limits and no apparent systematic pattern exists, then it can be assumed that the process is in control and the control limits can be used to evaluate future output from the process. However, if one or more sample statistic is outside the trial control limits, then they must be investigated for an assignable cause. If an assignable cause is established for those points outside the control limits, then they should be removed and new control limits should be computed. There are two options if an assignable cause cannot be attributed to those points plotted beyond the control limits. One option is to keep the out-of-control point(s) and continue on with the preliminary control limits. The second option is to delete the out-of-control point and recompute the control limits. If only one or two points are beyond the control limits, these two options will often produce similar results. It is standard practice to routinely revise the control limits. If there is a change in the process, then the control limits should definitely be revised. For example, if there were improvements made in the process that reduced variation, then the original control limits would be too wide and would not readily detect a shift in either the mean or the variability.

Many drug characteristics, such as potency, tablet weight, content uniformity, and dissolution, are measured on a continuous scale. The $\bar{X}$ and R chart are used to monitor the mean and the variability of a continuous variable. Fig. 6 provides an example of a $\bar{X}$ chart for dissolution. The formulas for constructing the control limits on the $\bar{X}$ chart are as follows:

$$\text{Upper Control Limit} = \bar{\bar{X}} + \frac{3}{d_2\sqrt{n}} \bar{R}$$

$$\text{Center Line} = \bar{\bar{X}}$$

$$\text{Lower Control Limit} = \bar{\bar{X}} - \frac{3}{d_2\sqrt{n}} \bar{R}$$

Fig. 6 An example of an $\bar{X}$ chart for dissolution

where $\bar{\bar{X}}$ represents the overall grand mean, d_2 is the constant depending on the sample size, n is the subgroup size, and $\bar{R}$ is the average within subgroup range.

An R chart can be used to monitor and to control process variability. R charts are constructed by plotting the sample ranges over time. Fig. 7 provides an R chart for the corresponding $\bar{X}$ chart mentioned above. The formulas for the R chart are as follows:

$$\begin{aligned}\text{Upper Control Limit} &= \bar{R}D_4 \\ \text{Center Line} &= \bar{R} \\ \text{Lower Control Limit} &= \bar{R}D_3\end{aligned}$$

where D_4 and D_3 are constants depending on the sample size. There are cases where the standard deviation can be used directly rather than using the range. If the sample size within a subgroup is relatively large (greater than 10), then the S chart is often recommended. The formulas for the S chart are as follows:

$$\begin{aligned}\text{Upper Control Limit} &= B_4\bar{S} \\ \text{Center Line} &= \bar{S} \\ \text{Lower Control Limit} &= B_3\bar{S}\end{aligned}$$

where B_3 and B_4 are constants depending on the sample size. The constants that are used to compute all the previously discussed control limits can be found in Montgomery,^[1] Ryan,^[5] or Wheeler.^[6]

Fig. 7 An example of an R chart for dissolution

Two aspects of control chart design to be considered are sample size and frequency of sampling. The choice of sample size and frequency of sampling will certainly depend on the amount of available resources. Given that there is a certain level of resources available for sampling/inspection, it must be decided how the sampling effort is allocated. Should one sample more frequently with a smaller sample size or sample less frequently with a larger sample size? The most accepted practice is to sample more frequently with a smaller sample size.

One way to formally determine the appropriate sample size and sampling frequency is via the *average run length* (ARL). The ARL is the average number of samples that must be plotted on the control chart before an out-of-control point is found after the process mean has undergone a meaningful shift. The ARL is equal to $1/p$, where p is the probability that the point is beyond the control limits, when the process mean has shifted a certain distance from the original mean. The value for p can be determined by an operating characteristic curve. Montgomery^[1] and Walpole et al.^[7] provide a nice discussion on operating characteristic curves. A performance measure that is often used to determine the sample size and sampling frequency is the *average time to signal* (ATS). The ATS, as the name indicates, is defined as the average time it will take for the control chart to detect a signal (out-of-control condition) when a given shift in the mean has occurred. Assume it is determined that, based on available resources, one can sample and test 10 items per hour. The question arises whether it would be more beneficial to sample five items every 30 minute or 10 items every hour. If the user is interested in detecting a 1.5σ shift in the mean, having a sample size of 10 per hour would produce an ATS of 1 hour, while a sample size of five per half hour would produce an ATS of approximately 45 minute. Operating characteristic curves can also be computed for the R chart, in order to detect a shift in variation. Montgomery^[1] and Walpole et al.^[7] provide a brief discussion on the operating characteristic curve for the R chart.

There are circumstances where no rational subgroup is available and the sample size used for process monitoring is $n = 1$ (e.g., composite assay on a given batch for product release). An individual (X) and moving range (MR) chart can be used when a subgroup of one is required. Because only one measurement is available at each sample, a moving range of two successive observations is used to estimate the process variability. The moving range is defined as $MR = |x_i - x_{i-1}|$. The formulas for constructing the control limits for the individuals chart are as follows:

$$\begin{aligned}\text{Upper Control Limit} &= \bar{\bar{X}} + 3 \frac{\text{mean}(\text{MR})}{d_2} \\ \text{Center Line} &= \bar{\bar{X}} \\ \text{Lower Control Limit} &= \bar{\bar{X}} - 3 \frac{\text{mean}(\text{MR})}{d_2}\end{aligned}$$

The control limits for the MR chart are analogous to the R chart, with the mean of the moving ranges used in place of the mean of the ranges. However, the MR chart does not allow one to truly evaluate the process variation. An example of an individual (X) and moving range chart for composite assay is provided in Fig. 8.

There are many quality measurements (e.g., cracked tablet, defective coating, split capsule, etc.) that are not numerical in nature, but rather are defined as an attribute. Attribute characteristics are defined as being defective or non defective. There are several standard control charts that handle attribute data. The first and most often used is a p chart, which is based on the binomial distribution, where p is the probability that any unit will not conform within the specification limits. The formulas for constructing the control limits for the p chart are as follows:

$$\begin{aligned}\text{Upper Control Limit} &= \bar{p} + 3\sqrt{\frac{\bar{p}(1-\bar{p})}{n}} \\ \text{Center Line} &= \bar{p} \\ \text{Lower Control Limit} &= \bar{p} - 3\sqrt{\frac{\bar{p}(1-\bar{p})}{n}}\end{aligned}$$

Fig. 9 provides an example of a p chart for coating defects. In the case where the defect level has a very low incidence rate ($p = 0.001$ or 1000 ppm), the p chart will often be of little use because most of the samples will have zero defects. Montgomery^[1] proposes to use the time between successive defects as the response. If the number of defects follows a Poisson distribution, then the time between defects follows an exponential distribution. An

Fig. 8 An example of individual and moving range chart for composite assay

Fig. 9 An example of a p chart for coating defects

np chart, which considers the number of nonconforming defects, and the c chart, which considers the number of defects per defined unit, are two additional control charts that are used in practice for attribute data. Montgomery,^[1] Ryan,^[5] and Wheeler^[6] provide more discussions on control charts for attributes.

Probably the most important aspect of control charts is to evaluate whether the process under study is out of control. A general guideline is that a process can be defined as out of control if one (or more) subgroup value is outside the control limits, or when the control chart demonstrates a non-random pattern. For example, eight consecutive subgroup values below the centerline would, in most cases, represent a non-random pattern. There are numerous patterns, which would provide evidence that the process is out of control, that could exist. Figs. 10–12 provide examples of non-random patterns. Fig. 10 represents an example where a shift in the process mean has occurred. The shift appears to have occurred at the 15th subgroup. Fig. 11 represents an example where the mean exhibits a cyclical pattern. Fig. 12 shows a range control chart that indicates that the variance of the process has shifted around the 12th subgroup. There are many rules for determining a non-random pattern (i.e., a process is out of control). Montgomery^[1] provides an extensive list of rules that can be used. Chow and Liu^[8] discuss some non-random patterns and the corresponding probability of the event occurring under normality. A very popular set of decision rules is provided by the Western Electric Handbook.^[9] One should be aware

Fig. 10 An example of a shift in the process mean

Fig. 11 An example of a cyclical pattern in the process mean for tablet weight

Fig. 12 An example of a shift in the process variance for tablet weight

that by using more decision rules, the probability of a false alarm significantly increases.

It is important to mention that both the process mean and the process variability need to be evaluated. There have been instances observed by the authors where the user considered only the $\bar{X}$ chart and mistakenly ignored the R chart. Often, one will evaluate the process variability before evaluating the process mean. If the R chart reveals an out-of-control condition, then the $\bar{X}$ chart should not be analyzed until the R chart has been rectified.

PROCESS CAPABILITY

Process capability is not an actual technique within the SPC tool bag; however, it is a critical component of statistical quality control. It is used to evaluate the process relative to specification limits. As previously mentioned, plotting a histogram along with the specification limits can be helpful in determining process capability. It has become common practice to use a single number (process capability indices) to quantify process capability. One of the most commonly used indices is the process capability ratio, which is defined as

$$C_p = \frac{USL - LSL}{6\sigma}$$

where USL and LSL are the upper specification limit and lower specification limit, respectively, and σ is the standard deviation computed from the control chart discussed in "Control Charts." The index C_p evaluates the spread of the distribution relative to the process range. A limitation of this index is that it does not address the location of the process mean relative to the specifications. A second commonly used capability index is the C_{pk} . This index accounts for the location of the process mean and provides a measure of how off-center the process is operating. It is defined as

$$C_{pk} = \min\left(\frac{USL - \mu}{3\sigma}, \frac{\mu - LSL}{3\sigma}\right)$$

It is our belief that confidence intervals of capability indices should become common practice when evaluating process capability. The confidence intervals should be used in order to account for the uncertainty because of sampling variability. Montgomery^[1] and Rodriguez^[10] discuss other capability indices, confidence intervals of capability indices, and procedure in assessing process capability when the quality measurement does not come from a normal distribution.

There are two very important assumptions that need to be made when presenting capability indices. They are that the quality measurement comes from a normal distribution, and that the process is in statistical control. If the quality measurement is not normally distributed, then the capability indices may not be very informative and could provide inaccurate estimates of defect levels. The normal distribution assumption can be evaluated by either histograms or goodness-of-fit tests. It is considered necessary that the process is in statistical control before evaluating process capability. If the process is not in statistical control, then the mean and/or variance is unstable and one may not be able to predict future process capability.

In the literature, there has been a discussion of the term process performance and how it differentiates from process capability. Breyfogle^[11] defines process performance as how well the process performs relative to the needs of the customer. Process performance indices use the standard deviation of the combination of all the data, which is used to estimate *long-term* variation. Long-term variation is a combination of both routine cause and special cause. So, instead of using the estimated standard from the control chart (e.g., $\bar{R}/d_2$), the sample standard deviation:

$$\sqrt{\sum_{i=1}^n (x_i - \bar{x})^2 / (n-1)}$$

is used to compute the process performance index. Montgomery^[1] mentions that some recommend using

process performance indices when the process is not in statistical control. However, there is much debate on the value of using process performance indices. Montgomery,^[1] Breyfogle,^[11] and Kotz and Lovelace^[12] provide some perspectives on the topic. However, if the performance index is used to quantify the performance of the process over a specified period of time and predicting future performance is not an immediate objective, then there appears to be some utility in process performance indices.

CONCLUSION

Statistical process control is an effective method for understanding and improving a process by finding assignable or special causes of variation and by removing them from the process. Histograms, Pareto charts, cause-and-effect diagrams, flowcharts, and control charts are SPC tools available to realize the goal of a stable and predictable process. Process capability indices are of use when a process is in control and future predictions about process capability need to be made. Process capability indices are of use when one wants to summarize the past performance of an in-control process or an out-of-control process. History has shown that SPC, when used diligently and effectively, can greatly enhance product quality and hence significantly contribute to a pharmaceutical company's success.

Statistical Significance

Dieter Hauschke

Byk Gulden Pharmaceuticals, Konstanz, Germany

Quintiles ClinData, Bloemfontein, South Africa

Abstract

This entry demonstrates that current statistical methodology can be applied to provide the necessary equivalence between statistical and clinical significance.

INTRODUCTION

Most controlled clinical trials are performed to demonstrate that a new investigational treatment is superior to a concurrent placebo or to an active control (superiority trials); that a test treatment is not inferior to an active treatment by more than a prespecified clinically irrelevant amount (noninferiority trials); or that two active treatments are therapeutically equivalent (equivalence trials). In the past, data from such trials have been usually analyzed by testing the traditional null hypothesis of no difference in the effect between the treatments. However, the most important drawback of this classical approach is the fact that looking only at the presence or absence of an effect ignores the issue of effect size. Hence, a statistically significant result gives only the information that the treatment difference is not zero but does not provide information as to the clinical relevance. Furthermore, failure to reject the null hypothesis does not imply the acceptance of the hypothesis of no difference. Therefore this practice has been criticized and the use of confidence intervals is advocated by regulatory guidelines.^[1,2] However, without the concept of the clinically significant (relevant) difference, the two methods are only technically different. Thus the adequate test problem should be formulated by incorporating the clinically significant difference, resulting in an equivalence of statistical and clinical significance. This direct approach will be demonstrated for superiority, noninferiority, and equivalence trials.

TESTING SHIFTED NULL HYPOTHESES

Proof of Superiority

A two-sample situation is considered. Let the clinical end point be denoted as X_1 for the test treatment and by X_0 for the control group. Suppose that these random variables are

mutually independent and have a continuous distribution function from a location family, that is,

$$X_{0j} \sim F(x - \mu_0) \quad \text{and} \quad X_{1j} \sim F(x - \mu_1), \\ j = 1, \dots, n_i, \quad i = 0, 1 \quad (1)$$

Without loss of generality, it is assumed that the population means are positive and that it is a priori known that if there is a favorable response to the treatment, it will increase in magnitude (i.e., $\mu_1 > \mu_0$), hence indicating the appropriateness of a one-sided alternative. It should be noted that the issue of a one-sided or a two-sided alternative is controversial as discussed in the literature, but this is outside our topic. Recently, the ICH guideline^[2] recommended the setting of the type I error for one-sided tests at half the conventional type I error used in two-sided testing. The traditional test problem of no difference is formulated as follows:

$$H_0 : \mu_1 - \mu_0 \leq 0 \\ H_1 : \mu_1 - \mu_0 > 0 \quad (2)$$

The rejection of the null hypothesis by a statistical test at level α (e.g., Student's t -test or Wilcoxon test) could provide evidence for the conclusion that there is a clinically relevant effect of the treatment. However, large sample sizes and little variation may lead to the problem that a clinically unimportant difference will be declared statistically significant. Suppose that a difference $\mu_1 - \mu_0 = \delta > 0$ is considered the maximum clinically irrelevant difference. If the true expected difference is less than or equal to this threshold value, then a statistically significant result for test problem 2 may be of little interest because the difference is not clinically significant. Consequently, the adequate test problem should be formulated as follows:

$$H_0^\delta : \mu_1 - \mu_0 \leq \delta \\ H_1^\delta : \mu_1 - \mu_0 > \delta \quad (3)$$

where $\delta, \delta > 0$ denotes the maximum clinically irrelevant difference. It should be noted that this definition implies that only differences greater than δ are regarded as clinically important. For example, the European guideline^[3] for chronic arterial occlusive disease requires that an irrelevant difference for the improvement in walking distance between the placebo and the new treatment should be excluded.

Assuming $F(x) = \Phi(x/\sigma)$, where $\Phi(\bullet)$ denotes the cumulative distribution function of the standard normal distribution, the shifted null hypothesis H_0^δ can be rejected if:

$$T^\delta = \frac{\bar{X}_1 - \bar{X}_0 - \delta}{S\sqrt{1/n_1 + 1/n_0}} \geq t_{\alpha, n_0+n_1-2} \quad (4)$$

where $t_{\alpha, \nu}$ is the $(1 - \alpha)$ percentile of the central t distribution with ν degrees of freedom; $\bar{X}_1$ and $\bar{X}_0$ denote the sample means of the treatment and control groups, respectively; and S_2 is the pooled estimator of σ^2 . Testing the nonzero null hypothesis (i.e., incorporating a shift parameter δ) permits the assessment of the clinical relevance of an observed treatment difference.^[4] Obviously, this decision procedure is equivalent to the condition that the lower limit of the one-sided $100(1 - \alpha)\%$ confidence interval is greater than δ , that is,

$$\left[\bar{X}_1 - \bar{X}_0 - t_{\alpha, n_0+n_1-2} S \sqrt{\frac{1}{n_0} + \frac{1}{n_1}}, \infty \right) \subset (\delta, \infty) \quad (5)$$

The exact sample size to attain a prespecified power of $1 - \beta$ for a given level α , a standard deviation σ , and an important value $\mu_1 - \mu_0 = \delta_1 > \delta$, which should not be overlooked, can be directly obtained from the univariate noncentral t distribution or can be approximated for the balanced design (i.e., $n_0 = n_1 = n$) as follows:

$$n \geq 2 \left(\frac{(t_{\alpha, 2n-2} + t_{\beta, 2n-2}) \sigma}{\delta_1 - \delta} \right)^2 \quad (6)$$

The corresponding nonparametric method for testing the shifted hypothesis using the Wilcoxon rank sum statistic $R_1(\delta) = \sum_{j=1}^{n_1} R_{1j}(\delta)$ is presented in Hollander and Wolfe^[5] and is based on the ranks $R_{1j}(\delta)$ of the shifted observations in the treatment group in the combined sample:

$$X_{11} - \delta, \dots, X_{1n_1} - \delta, X_{01}, \dots, X_{0n_0} \quad (7)$$

H_0^δ is rejected if $R_1(\delta) \geq r(\alpha, n_0, n_1)$, where $r(\alpha, n_0, n_1)$ is the $(1 - \alpha)$ percentile of the Wilcoxon rank statistic $R_1(\delta)$. The calculation of this confidence interval according to Hollander and Wolfe^[5] can be performed as follows. Let $D_1 \leq \dots \leq D_{n_0 n_1}$ denote the ordered values of the $n_0 n_1$ differences $X_{1j} - X_{0j^*}$, $j = 1, \dots, n_1$ and $j^* = 1, \dots, n_0$. The median of these pairwise differences serves as the Hodges–Lehmann

estimator^[6] and the lower limit of the one-sided $100(1 - \alpha)\%$ confidence interval for $\mu_1 - \mu_0$ is given by:

$$L = D_{C_\alpha}, \quad \text{where } C_\alpha = \frac{n_1(2n_0 + n_1 + 1)}{2} + 1 - r(\alpha, n_0, n_1) \quad (8)$$

Appropriate methods for power calculation and necessary sample sizes for nonparametric procedures are given by Noether^[7] and Collings and Hamilton.^[8]

It should be noted that the use of p values and hypothesis tests in the analysis of medical data has been criticized, and point estimates and confidence intervals have been proposed. Nevertheless, it is possible to evaluate the results of clinical studies appropriately using hypothesis tests, as long as relevant hypotheses like those in Eq. (3) are tested, and not the meaningless hypothesis of Eq. (2). However, although there is nothing wrong with testing relevant hypotheses and reporting the associated p value, the use of point estimates and confidence intervals has two advantages. First, as already shown, the shifted hypotheses can conveniently be evaluated using confidence intervals. Second, point estimates and confidence intervals provide direct information about the magnitude of the treatment difference; this may be easier to interpret than p values, which express the magnitude on the probability scale.

The specification of δ requires that statisticians and clinicians think about what constitutes a maximum clinically irrelevant difference, and a common situation in practice is that the value δ is expressed as a proportion of the unknown population mean μ_0 . Therefore assuming that $\delta = f\mu_0$, $f > 0$, the test problem 3 can be formulated as:

$$\begin{aligned} H_0^\delta : \mu_1 - \mu_0 &\leq f\mu_0 \\ H_1^\delta : \mu_1 - \mu_0 &> f\mu_0 \end{aligned} \quad (9)$$

or as

$$\begin{aligned} H_0^\theta : \frac{\mu_1}{\mu_0} &\leq \theta \\ H_1^\theta : \frac{\mu_1}{\mu_0} &> \theta \end{aligned} \quad (10)$$

where $\theta = 1 + f$, $\theta > 1$, is the corresponding maximum clinically irrelevant value for μ_1/μ_0 . Under the assumption of normality and common variance, Sasabuchi^[9] demonstrated that the size- α likelihood ratio test rejects the shifted null hypothesis H_0^θ concerning the ratio of the two means if:

$$T^\theta = \frac{\bar{X}_1 - \theta \bar{X}_0}{S\sqrt{1/n_1 + \theta^2/n_0}} \geq t_{\alpha, n_0+n_1-2} \quad (11)$$

Algebraic rearrangement shows that condition 11 is equivalent to:

$$\begin{aligned} \theta_- \geq \theta \text{ and } \bar{X}_0^2 > a_0, \\ \text{where } \theta_- = \frac{\bar{X}_0 \bar{X}_1 - \sqrt{a_0 \bar{X}_1^2 + a_1 \bar{X}_0^2 - a_0 a_1}}{\bar{X}_0^2 - a_0}, \quad (12) \\ a_0 = \frac{S^2}{n_0} t_{\alpha, n_0 + n_1 - 2}^2, \quad \text{and} \quad a_1 = \frac{S^2}{n_1} t_{\alpha, n_0 + n_1 - 2}^2 \end{aligned}$$

Condition 12 can be interpreted as follows: If the lower limit of the one-sided $100(1 - \alpha)$ Fieller^[10] confidence set for μ_1/μ_0 is finite, the interval is given by $I_F = (\theta_-, \infty)$. Furthermore, Fieller's one-sided confidence set is a lower bounded interval if and only if $\bar{X}_0^2 > a_0$ holds true. Hence, the following two procedures for the assessment lead to the same decisions: (1) conclude superiority if and only if H_0^θ is rejected by the level α Sasabuchi test; and (2) conclude superiority if and only if the lower limit of the one-sided $100(1 - \alpha)\%$ Fieller confidence interval is above θ .

The following approximate formula for a balanced sample size determination to attain a prespecified power of $1 - \beta$ for a given level α , a coefficient of variation $CV_0 = \sigma/\mu_0$, and a value from the alternative $\mu_1/\mu_0 = \theta_1 > \theta$ was given by Hauschke et al.:^[11]

$$n \geq (1 + \theta^2) \left(\frac{(t_{\alpha, 2n-2} + t_{\beta, 2n-2}) CV_0}{\theta_1 - \theta} \right)^2 \quad (13)$$

It should be noted that a short discussion of corresponding nonparametric methods was provided by Vuorinen and Turunen,^[12] but further research on this issue still needs to be performed.

Proof of Noninferiority

The most convincing way to establish the efficacy of a new investigational treatment is to demonstrate clinically relevant superiority to a concurrent placebo group. In the case where an accepted treatment exists, the comparison against placebo may be considered unethical. Furthermore, when a new treatment has certain advantages, such as fewer side effects or simpler application, it might be enough to show that the test treatment is not relevantly inferior to the comparator. The choice of the extent of irrelevant inferiority should be based on clinical reasoning and will require researchers to think about what constitutes a clinically relevant difference. The corresponding hypothesis and alternative can be written as:

$$\begin{aligned} H_0^\delta : \mu_1 - \mu_0 \leq \delta^* \\ H_1^\delta : \mu_1 - \mu_0 > \delta^* \end{aligned} \quad (14)$$

where $\delta^*, \delta^* < 0$ denotes the maximum clinically irrelevant difference. Analogous to the previously given methodology for superiority trials, this shifted null hypothesis can be tested and the adequate sample size determination can be performed.

Proof of Equivalence

Many clinical trials aim to show equivalence between a test treatment under development and an existing reference treatment. In such studies, the issue is no longer to detect a difference but to demonstrate that the two active treatments are equivalent within a priori stipulated margins. A widespread application of this problem is the assessment of comparative bioavailabilities in a bioequivalence trial. Let the interval (δ_1, δ_2) denote the prespecified equivalence range; the corresponding test problem is formulated as follows:

$$\begin{aligned} H_0^\delta : \mu_1 - \mu_0 \leq \delta_1 \text{ or } \mu_1 - \mu_0 \geq \delta_2 \\ H_1^\delta : \delta_1 < \mu_1 - \mu_0 < \delta_2 \end{aligned} \quad (15)$$

Under normality and by assuming that the margins δ_1 and δ_2 are known, H_0^δ can be rejected at level α in favor of H_1^δ (equivalence) if the parametric two-sided $100(1 - 2\alpha)\%$ confidence interval for $\mu_1 - \mu_0$ is entirely included in the equivalence range:

$$\left[\bar{X}_1 - \bar{X}_0 \pm t_{\alpha, n_0 + n_1 - 2} S \sqrt{\frac{1}{n_0} + \frac{1}{n_1}} \right] \subset (\delta_1, \delta_2) \quad (16)$$

This procedure is equivalent to the two one-sided tests procedure by means of shifted two-sample t -tests.^[13] It should be noted that the corresponding nonparametric test procedure and the corresponding confidence interval construction were provided by Hauschke et al.^[14]

In the following, the equivalence limits δ_1 and δ_2 are again defined as proportions of the unknown mean μ_0 . Suppose that $\delta_1 = f_1 \mu_0$ and $\delta_2 = f_2 \mu_0$, where $-1 < f_1 < 0 < f_2$. For example, $f_1 = -f_2 = -0.20$ corresponds to the common $\pm 20\%$ criteria. The foregoing test problem can be formulated as:

$$\begin{aligned} H_0^\theta : \frac{\mu_1}{\mu_0} \leq \theta_1 \text{ or } \frac{\mu_1}{\mu_0} \geq \theta_2 \\ H_1^\theta : \theta_1 < \frac{\mu_1}{\mu_0} < \theta_2 \end{aligned} \quad (17)$$

where (θ_1, θ_2) , $\theta_1 = 1 + f_1$, $\theta_2 = 1 + f_2$, $0 < \theta_1 < 1 < \theta_2$, is the corresponding equivalence interval for the ratio μ_1/μ_0 . Testing this two-sided equivalence problem is equivalent

to the simultaneous testing of the following two one-sided hypotheses:

$$\begin{aligned} H_{01}^{\theta} : \frac{\mu_1}{\mu_0} \leq \theta_1 & \quad H_{02}^{\theta} : \frac{\mu_1}{\mu_0} \geq \theta_2 \\ \text{and} & \\ H_{11}^{\theta} : \frac{\mu_1}{\mu_0} > \theta_1 & \quad H_{12}^{\theta} : \frac{\mu_1}{\mu_0} < \theta_2 \end{aligned} \quad (18)$$

The size- α likelihood ratio test rejects H_{01}^{θ} and H_{02}^{θ} if:

$$\begin{aligned} T_1^{\theta} &= \frac{\bar{X}_1 - \theta_1 \bar{X}_0}{S \sqrt{1/n_1 + \theta_1^2/n_0}} \geq t_{\alpha, n_0+n_1-2} \quad \text{and} \\ T_2^{\theta} &= \frac{\bar{X}_1 - \theta_2 \bar{X}_0}{S \sqrt{1/n_1 + \theta_2^2/n_0}} \leq -t_{\alpha, n_0+n_1-2} \end{aligned} \quad (19)$$

The algebraic rearrangement shows that condition 19 is equivalent to:

$$\begin{aligned} \theta_- \geq \theta_1 \quad \text{and} \quad \theta_+ \leq \theta_2 \quad \text{and} \quad \bar{X}_0^2 > a_0, \\ \text{where } \theta_{\pm} &= \frac{\bar{X}_1 \bar{X}_0 \pm \sqrt{a_0 \bar{X}_1^2 + a_1 \bar{X}_0^2 - a_0 a_1}}{\bar{X}_1^2 - a_0}, \\ a_0 &= \frac{S^2}{n_0} t_{\alpha, n_0+n_1-2}^2, \quad \text{and} \quad a_1 = \frac{S^2}{n_1} t_{\alpha, n_0+n_1-2}^2 \end{aligned} \quad (20)$$

Condition 20 can be interpreted as follows: If the two-sided $100(1 - 2\alpha)\%$ Fieller confidence set for μ_1/μ_0 has finite length, it is given by the interval $I_F = (\theta_-, \theta_+)$. Furthermore, Fieller's confidence set is an interval if and only if $\bar{X}_0^2 > a_0$ holds true. Hence the following two procedures for assessing test problem 17 lead to the same decisions: (1) conclude equivalence if and only if H_{01}^{θ} and H_{02}^{θ} are rejected by the level α Sasabuchi tests; and (2) conclude equivalence if and only if the two-sided $100(1 - 2\alpha)\%$ Fieller confidence interval is included in the equivalence range.

The problem of exact power calculation and sample size determination under the assumption of normality was addressed by Hauschke et al.^[15] The following approximate formulas for sample size determination were given by Kieser and Hauschke,^[16] assuming $\theta_1 = 1/\theta_2$ and $\theta^* = \mu_1/\mu_2$:

$$\begin{aligned} \text{if } \theta^* = 1 \quad n &\geq (1 + \theta_2^2) (t_{\alpha, 2n-2} + t_{\beta/2, 2n-2})^2 \times \left(\frac{CV_0}{1 - \theta_2} \right)^2 \\ \text{if } 1 < \theta^* < \theta_2 \quad n &\geq (1 + \theta_2^2) (t_{\alpha, 2n-2} + t_{\beta, 2n-2})^2 \times \left(\frac{CV_0}{\theta_2 - \theta^*} \right)^2 \\ \text{if } \frac{1}{\theta_2} < \theta^* < 1 \quad n &\geq \left(1 + \frac{1}{\theta_2^2} \right) (t_{\alpha, 2n-2} + t_{\beta, 2n-2})^2 \times \left(\frac{CV_0}{1/\theta_2 - \theta^*} \right)^2 \end{aligned} \quad (21)$$

Wider Applications

In the preceding sections, the evaluation of study results using shifted hypothesis testing and confidence intervals was described when the focus of interest was a difference or a ratio of treatment means. A similar approach can be used in other cases. For example, when a difference between two proportions, such as the proportion of patients with a positive outcome for two treatments, is the focus of interest, then the shifted hypotheses can be modified by replacing μ_1 and μ_0 by π_1 and π_0 . The same approach can be adopted for the ratio of proportions (i.e., the relative risk).^[17]

CONCLUSION

Testing a nonzero null hypothesis instead of one of no treatment difference removes at a stroke some logical problems. For example, one problem of testing the classical null hypothesis is that even for the most minute true difference between two treatments, the p value will indicate statistical significance if the sample size is big enough. When data are analyzed by testing shifted hypotheses, or through confidence intervals as outlined, then an increase in sample size or in the precision of the data, or both, will lead to a narrowing of the confidence interval and thus to an increase in the probability of obtaining a conclusive result (i.e., a statistically and clinically relevant significance). This entry demonstrates that current statistical methodology can be applied to provide the necessary equivalence between statistical and clinical significance.

Structural Equation Model

Joseph L. Carrasco

Bioestadística, Universitat de Barcelona, Barcelona, Spain

Abstract

This entry examines the simple linear structural equation with a dependent variable and an independent variable with measurement error. It also shows how the structural equation model can be applied to individual bioequivalence assay.

Keywords: Individual bioequivalence; Latent variable; Measurement error; Measurement method comparison; Orthogonal regression; Reliability; Structural relationship.

INTRODUCTION

The structural equation model is a regression approach that allows to estimate a linear regression when independent variables are measured with error. The approach is based on defining latent variables, which represent unobservable true values; thus the model considers that the observed data are the result of adding the measurement error to the *true values*. Moreover, the relationship between the true values of the independent and dependent variables is defined through the structural equation.

The classical regression models do not take into account the measurement error of the independent covariates, thus giving biased estimators of slopes.

Here, we examine the simple linear structural equation with a dependent variable and an independent variable with measurement error. We also show how the structural equation model can be applied to individual bioequivalence assay.

STRUCTURAL EQUATION MODEL

The classical regression model links a dependent variable or outcome to a vector of independent or explanatory variables. This model assumes that the explanatory variables are measured with no error and that the only random variation is in the outcome conditioned to the explanatory variables. However, there are situations where this assumption may not be valid. For example, let us suppose that we want to estimate the relationship between the levels of a hormone with respect to the intake of alcohol and age. In this situation, a sample of subjects is collected and the blood concentration of the hormone, the weekly intake of alcohol, and the age of the subjects are measured. It appears that the age of the subjects can be measured with no error, at least if it is rounded to years, but the same cannot be

said of the intake of alcohol. This variable will probably be measured by using a questionnaire where the subjects declare their alcohol consumption in the last week. Even if the subjects are completely sincere, the amount of alcohol declared will be an approximation of the real quantity; therefore the intake of alcohol will be measured with error. Thus if the relationship between the outcome and the explanatory variable is estimated using an approach that does not take into account the measurement error (such as ordinary least squares), such estimators will be biased and inconsistent.^[1]

The structural equation model is a regression approach that estimates the model by taking into account that the independent variables are measured with error. For that reason, the structural equation model is also called measurement error regression, or error-in-variables regression.

Here, only the simple linear structural equation with an explanatory variable will be considered, but there are extensions to more complex models, including several dependent variables^[2] and nonlinear relationships.^[3]

THE MODEL

Let Y_i be an outcome and let X_i be an explanatory variable measured on the i th subject, where $i = 1, \dots, n$. The simple structural equation model is defined as:^[4]

$$\begin{aligned} Y_i &= \eta_i + \varepsilon_i \\ X_i &= \xi_i + \delta_i \\ \eta_i &= \alpha + \beta \xi_i \end{aligned}$$

where Y and X are the observed data, η and ξ are the *true values* or latent variables, and ε and δ are the measurement errors. The parameters α and β characterize the structural equation, which is no more than the linear relationship between the latent variables.

It is usually assumed that the measurement errors do not covary with any other component of the model, and that they are distributed under normal distributions with mean 0 and standard deviations σ_ε and σ_δ , respectively. It is also assumed that the latent variable ξ is distributed under a normal distribution, with mean μ and standard deviation σ .

Thus the structural equation determines the relationship between the means of the variables and the covariance structure. The mean of Y can be expressed as:

$$E(Y) = E(\eta + \varepsilon) = E(\alpha + \beta\xi + \varepsilon) = \alpha + \beta E(\xi) + E(\varepsilon) = \alpha + \beta\mu$$

which is the same result as that achieved with the classical regression model. But there are differences in the covariance structure because:^[4]

$$Var(Y) = Var(\eta + \varepsilon) = Var(\alpha + \beta\xi + \varepsilon) = \beta^2\sigma^2 + \sigma_\varepsilon^2$$

$$Var(X) = Var(\xi + \delta) = Var(\xi) + Var(\delta) = \sigma^2 + \sigma_\delta^2$$

$$cov(Y, X) = cov(\eta + \varepsilon, \xi + \delta) = \beta\sigma^2$$

Thus the slope of the structural equation is not only involved in the mean but also in the variance and covariance. Moreover, the slope also defines the relationship between the standard deviations of the latent variables:

$$Var(\eta) = Var(\alpha + \beta\xi) = \beta^2 var(\xi)$$

$$\beta = \sqrt{\frac{Var(\eta)}{Var(\xi)}}.$$

Therefore there are six parameters that define the model and have to be estimated: μ , σ , α , β , σ_ε , and σ_δ .

The estimation of parameters can be carried out by maximum likelihood, but, unfortunately, there are more parameters to estimate than there are estimating equations (i.e., there is not enough information in the data to allow the estimation of parameters). This problem is known as a lack of identification of the model.

The model becomes identified by incorporating information on some of the parameters. Traditionally, five cases can be found in the literature:^[5]

1. The ratio of the error variances $\lambda = \sigma_\varepsilon^2 / \sigma_\delta^2$ is known.
2. Both of the error variances are known.
3. σ_δ^2 is known.
4. σ_ε^2 is known.
5. The intercept α is known.

Probably, the most commonly used assumption is the case where the ratio of error variances is known and is equal to 1, perhaps because it is the first assumption ever used in structural equation models.^[6] This case has been also called orthogonal regression or principal component model^[7] because the orthogonal distances from the pair of points to the regression line are minimized.

The expression of the estimates and their standard errors will rely on the assumption made. A summary of the estimates and the variance-covariance matrix for each case can be found in Ref. [8].

It is possible to achieve identification by taking replicates (measuring individuals more than once) of Y and/or X and by using them to estimate the measurement error variances.^[9] Once the error variances have been estimated, they can be considered as known, and the estimation of the remaining parameters becomes feasible.^[12,9] Depending on whether the replicates are taken on one or both variables, cases (2), (3), or (4) can be applied. This approach is known as partial likelihood analysis^[9] because full log likelihood is expressed as the sum of a conditional log likelihood and a marginal log likelihood. For the case of both variances known, the log likelihood can be expressed as:

$$\log L(\alpha, \beta, \sigma^2, X_{ij}, Y_{ij}, \sigma_\delta^2, \sigma_\varepsilon^2) = \log L(\alpha, \beta, \sigma^2 | \bar{X}_i, \bar{Y}_i, \sigma_\delta^2, \sigma_\varepsilon^2) + \log L(W_X, W_Y, \sigma_\delta^2, \sigma_\varepsilon^2)$$

where

$$\begin{aligned}\bar{X}_i &= \frac{1}{k} \sum_{j=1}^k X_{ij} \\ \bar{Y}_i &= \frac{1}{k} \sum_{j=1}^k Y_{ij} \\ W_X &= \sum_{i=1}^n \sum_{j=1}^k (X_{ij} - \bar{X}_i)^2 \\ W_Y &= \sum_{i=1}^n \sum_{j=1}^k (Y_{ij} - \bar{Y}_i)^2\end{aligned}$$

and $i = 1, \dots, n$ and $j = 1, \dots, k$, where n is the number of subjects and k is the number of replicates. Thus the conditional log likelihood depends on individual means and within-subject variances, whereas marginal log likelihood relies on within-subject deviations. Then within-subject variances are estimated by:

$$\sigma_\delta^2 = \frac{W_X}{n(k-1)}$$

$$\sigma_\varepsilon^2 = \frac{W_Y}{n(k-1)}$$

and incorporated in the conditional log likelihood as known, and the remaining parameters are estimated through the conditional log likelihood.

The estimates follow an asymptotic normal distribution;^[4] thus building confidence intervals or testing hypotheses can be performed by using a normal distribution, although Fuller^[2] recommend a t student distribution for small samples.

However, there is a problem with the confidence interval estimation of β , which is known as the Gleser-Hwang effect. Gleser and Hwang^[10] demonstrated that when the

number of subjects is fixed, every confidence interval for β , of finite length, has a confidence equal to 0. Nevertheless, Gleser^[11] showed that if the quantity known as signal-to-noise, $\kappa^2 = \sigma^2/\sigma_\delta^2$ and the number of subjects are large enough ($\kappa^2 \geq 1$ and more than 25 subjects), asymptotic confidence is reasonably close to the desired coverage probability. The heuristic rationale could be that we are trying to estimate the relationship between two variables that are *contaminated* by some noise (measurement error). Of course, the greater is the noise, the more difficult it will be to estimate this relationship and more *signal* will be required. The signal can be understood as the variability between subjects, so that, if the noise is large, more subjects with a greater spread of values will be required.

The maximum likelihood approach gives consistent and efficient estimates, but it relies on the normality assumption of the data. Other estimation procedures do not depend on such an assumption; thus they are more robust to departures from normality. However, if data are normally distributed, the maximum likelihood estimates are the most efficient.

Among these procedures, we would like to highlight the generalized least squares, the instrumental variables approach, and methods based on ranks.

The generalized least squares or weighted least squares^[12] consist of minimizing square distances from points to the regression line by using weights. These weights are taken to be proportional to the reciprocal of variance errors: $1/(\sigma_e^2 + \beta^2 \sigma_\delta^2)$. Nevertheless, it has been demonstrated that the generalized least squares approach is no more than the classical orthogonal regression.^[4]

The instrumental variables approach is useful in any regression model where the independent variable is correlated with the error. The structural model is an example of this kind of regression because the explanatory variable X is correlated with the error of the regression line. This fact can be easily seen if the structural model is expressed as: $Y = \alpha + \beta X + e$, $e = \varepsilon - \beta\delta$ then $cov(X, e) = cov(\xi + \delta, \varepsilon - \beta\delta) = -\beta cov(\delta, \delta) = -\beta\sigma_\delta^2$.

The instrumental variables approach^[13] consists of finding a variable, say Z , that is correlated with the independent variable X but uncorrelated with the error e . This variable can be continuous, discrete, or a factor. Then the estimator of the slope is:

$$\hat{\beta}_V = \frac{cov(Z, Y)}{cov(Z, X)}$$

However, the use of instrumental variables has been criticized because of the difficulty of finding such a variable,^[3,5] and in the words of Cheng and Van Ness,^[4] “the justification of using instrumental variables is based on consistency considerations only, and this does not guarantee good performance in applications involving large sample variances and moderate sample sizes, in which the consistency properties cannot be brought to bear.”

Moreover, the selection of instrumental variables might not be unique. Then, in the same analysis, it would be possible to choose different instrumental variables that would give different estimates.

The methods based on ranks^[14,15] can be viewed as a special case of instrumental variables, where the instrumental variable used is the order statistic. Although this is a robust approach, there is an underlying assumption about the distribution of the true values. The X values must be of the same order as the true values; therefore the true values must be more widely distributed than the error variance.

STRUCTURAL EQUATION MODEL APPLIED TO BIOEQUIVALENCE

Structural equation models have been applied to several fields. As examples, we would like to highlight reliability studies,^[16] analytical methods comparison,^[7,15] health sciences,^[17–9] and behavioral sciences.^[20,21]

In the pharmaceutical field, the structural equation model has also been applied to evaluate individual bioequivalence.^[22] The aim of a bioequivalence assay is to demonstrate that a reference (R) and a tested (T) formulation are equal with respect to their safety and efficacy—this objective is achieved if the two formulations have the same amount of bioavailabilities.

Bioequivalence assays are typically based on models of the logarithm of bioavailability measurements. The measurement model proposed for bioavailabilities (or its log-transformed values) is:^[23] $T_{ij} = \mu_T + u_{Ti} + e_{Tij}$; $R_{ij} = \mu_R + u_{Ri} + e_{Rij}$ where T_{ij} and R_{ij} are the bioavailabilities of tested (T) and reference (R) formulations; μ_T and μ_R are the overall averages of T and R; u_{Ti} and u_{Ri} are the mean deviations of individual i with respect to the overall mean; and e_{Tij} and e_{Rij} are the random deviations of individual i on j th determination, where $i = 1, \dots, n$ and $j = 1, \dots, k$. Hereinafter, we will refer to u_{Ti} and u_{Ri} as between-subject deviations, and e_{Tij} and e_{Rij} as within-subject deviations. It is assumed that both between-subject and within-subject deviations are distributed under normal distributions with parameters:

$$u_T \sim N(0, \sigma_{BT}), u_R \sim N(0, \sigma_{BR}), \\ e_T \sim N(0, \sigma_{WT}), e_R \sim N(0, \sigma_{WR})$$

It is also assumed that the within-subject deviations do not covariate with any parameter.

Individual bioequivalence requires a certain degree of agreement between the bioavailabilities of two formulations: the overall averages, the between-subject deviations, and the variability of the within-subject deviations have to be close enough.

From the measurement model for bioavailabilities, we can define a structural model equation. Because the between-subject deviations u_T and u_R are unknown and

unobservable, they can be considered as latent variables, and the within-subject deviations can be considered as some noise around the latent variable. Then, the structural equation is defined as: $u_{T_i} = \alpha + \beta u_{R_i}$.

The requirements to guarantee that the bioavailabilities are close enough can be summarized in three points:

1. The difference between overall means is within some interval, around $0\phi = \mu_T - \mu_R = \alpha + (\beta - 1)\mu_R \in [\theta_A, \theta_B]$
2. The slope of the structural equation is within some interval, around 1 $\beta \in [\theta_C, \theta_D]$
3. The ratio of within-subject variances is below some limit $\lambda = \sigma_{WT}^2 / \sigma_{WR}^2 \leq \theta_E$

where, depending on the values of θ_A , θ_B , θ_C , θ_D , and θ_E , the criteria will be more or less restrictive.

Therefore the hypothesis of individual bioequivalence will be tested in a disaggregated sense by evaluating five hypotheses about ϕ , β , and λ :

$$H_{01} : \phi < \theta_A, H_{02} : \phi > \theta_B, H_{03} : \beta < \theta_C, H_{04} : \beta > \theta_D, H_{05} : \lambda > \theta_E$$

$$H_{11} : \phi \geq \theta_A, H_{12} : \phi \leq \theta_B, H_{13} : \beta \geq \theta_C, H_{14} : \beta \leq \theta_D, H_{15} : \lambda \leq \theta_E$$

Thus the overall hypothesis of individual bioequivalence is expressed as:

$$H_0 : \text{No bioequivalence} = H_{01} \cup H_{02} \cup H_{03} \cup H_{04} \cup H_{05}$$

$$H_1 : \text{Bioequivalence} = H_{11} \cap H_{12} \cap H_{13} \cap H_{14} \cap H_{15}$$

This sort of mixed hypothesis is tested using the *intersection-union principle* of Roy.^[24] Following this principle, the null hypothesis of no bioequivalence is rejected with a significance level α if all null hypotheses are rejected at level α .

The hypotheses concerning β and ϕ can be tested in a *two one-sided way*^[25] by using interval estimation with a confidence of $1 - 2\alpha$, with α as the desired significance level. If the whole confidence interval lies within the bioequivalence limits, both null hypotheses will be rejected.

The hypothesis concerning within-subject variances can be tested by estimating the $1 - \alpha$ percentile of λ , with α as the desired significance level. This percentile is estimated as: $\hat{\lambda}F_{1-\alpha, v_1, v_2}$ where $F_{1-\alpha, v_1, v_2}$ is the $1 - \alpha$ percentile of F distribution with: $v_1 = v_2 = n(k - 1)$ degrees of freedom, where k is the number of measures by subject and formulation, and n is the number of subjects.

EXAMPLE

As an example to illustrate the structural equation model applied to bioequivalence data, we will use data from a β -adrenergic blocking agent (Table 1). The bioavailabilities were measured on 22 subjects using a four-period, four-sequence replicated crossover design. Therefore two measures of formulation and subject are available; thus it

is possible to estimate both within-subject variances. The bioavailability measure used was the area under the curve (AUC), and its logarithm was taken.

The estimates of the within-subject variances were:

$$\hat{\sigma}_{WT}^2 = 0.1453 \quad \hat{\sigma}_{WR}^2 = 0.0334$$

$$\hat{\lambda} = \frac{0.1453}{0.0334} = 4.3458$$

These variances are implemented as known parameters in the conditional log likelihood. The overall means, variances, and covariances of the individual means are:

$$\bar{X}_R = \frac{1}{22} \sum_{i=1}^{22} \bar{R}_i = 8.448$$

$$\bar{X}_T = \frac{1}{22} \sum_{i=1}^{22} \bar{T}_i = 8.3393$$

$$S_R^2 = \text{Var}(\bar{R}_i) = 0.1398$$

$$S_T^2 = \text{Var}(\bar{T}_i) = 0.1894$$

$$S_{RT} = \text{cov}(\bar{R}_i, \bar{T}_i) = 0.1237$$

The estimates of the remaining parameters are:^[19]

$$\hat{\beta} = \frac{S_T^2 - \hat{\lambda}S_R^2 + \left[(S_T^2 - \hat{\lambda}S_R^2)^2 + 4\hat{\lambda}S_{RT}^2 \right]^{1/2}}{2S_{RT}} = 0.9938$$

$$\hat{\alpha} = \bar{X}_T - \hat{\beta}\bar{X}_R = -0.0562$$

$$\hat{\sigma}_{BR}^2 = \frac{S_T^2 + \hat{\lambda}S_R^2 - \hat{\sigma}_{WT}^2 + [(S_T^2 - \hat{\lambda}S_R^2)^2 + 4\hat{\lambda}S_{RT}^2]^{1/2}}{2(\hat{\lambda} + \hat{\beta}^2)} = 0.1233$$

To contrast the hypotheses related to individual bioequivalence, it is necessary to define the bioequivalent limits, which depend on how restrictive the criterion should be. A proposal could be:

$$\theta_A = -\log 1.25 \quad \theta_B = \log 1.25 \quad \theta_C = 2/3$$

$$\theta_D = 1.5 \quad \theta_E = 2.25$$

The values of θ_A and θ_B come from the average bioequivalence criterion;^[26] θ_C and θ_D are set using the fact that β is the ratio of between-subject standard deviations. Thus any standard deviation cannot exceed the other by more than 1.5 times. This criterion is also used for the ratio of within-subject variances, but here, it is only necessary that the within-subject variance of the tested formulation does not exceed the within-subject variance of reference formulation by more than 2.25 times (1.5 in standard deviation scale).

First, the hypothesis relating to the difference of overall averages will be tested. In this order, a 90% confidence interval is built as: $\hat{\phi} \pm t_v SE(\hat{\phi})$ where $\hat{\phi} = \hat{\mu}_T - \hat{\mu}_R = \hat{\alpha} + (\hat{\beta} - 1)\hat{\mu}_R = -0.1088$ t_v means a t

11	R	8095.60	22	T	2677.48

All subjects were measured twice in both reference (R) and tested (T) formulations.

distribution with $v = n - 2$ degrees of freedom, with n as the number of subjects; therefore $v = 20$. The standard error of the difference of means is:^[22]

$$Var(\hat{\phi}) = \frac{\sigma_{WT}^2 + \beta^2 \sigma_{WR}^2}{kn}$$

with k as the number of measures by subject and formulation (in this case, $k = 2$). Then: $SE(\hat{\phi}) = 0.0637$ and the 90% confidence interval becomes $[-0.2186; 0.0010]$, which is completely within the bioequivalent limits; thus both hypotheses concerning difference of means are rejected.

In relation to the slope, the 90% confidence interval is built using: $\hat{\beta} \pm t_v SE(\hat{\beta})$ and, in that case, the standard error of the slope is expressed by:

$$Var(\hat{\beta}) = \frac{1}{n\sigma_{BR}^4} \left(\theta \left(\sigma_{BR}^2 + \frac{\sigma_{WR}^2}{k} \right) - \beta^2 \left(\frac{\sigma_{WR}^2}{k} \right)^2 \right)$$

where $\theta = \frac{1}{k} (\sigma_{WT}^2 + \beta^2 \sigma_{WR}^2)$

The estimate of the standard error is 0.1910; thus the 90% confidence interval for β is $[0.6642; 1.3333]$. The lower limit exceeds the bioequivalent limit. Thus one of the hypotheses concerning β is not rejected.

Finally, the hypothesis on λ is tested by estimating the 95th percentile of the λ estimate. This percentile is estimated by using an F distribution with $n(k-1)$ and $n(k-1)$ degrees of freedom; therefore: $per95(\hat{\lambda}) = \hat{\lambda} per95(F_{22,22}) = 8.8991$ which is greater than the bioequivalent limit; thus the null hypothesis is rejected.

We conclude that the two formulations are not individually bioequivalent, but a structural equation model allows a disaggregate analysis, thereby making it possible to discuss the sources of nonbioequivalence.

In this example, we have shown that the difference in overall averages is low enough to conclude that they are equivalent. However, the between-subject variances are not equivalent. The large variability of the β estimate, combined with a point estimate close to 1, indicates a problem of lack of power: more subjects were needed to make a decision. Indeed, the number of 22 subjects is quite low to achieve a high degree of power. Carrasco and Jover^[22] carried out a power analysis by arriving at the conclusion that between 50 and 100 subjects is necessary to guarantee a certain degree of power. However, the within-subject variance of the tested formulation is clearly greater than the within-subject variance of the reference formulation, this being the main reason to reject the individual bioequivalence.

CONCLUSION

Structural equation modeling is a useful regression approach when the independent variables are measured

with a nonnegligible measurement error. If this measurement error is not taken into account, the estimates of the slopes and their standard errors will be biased.

Here the simple normal structural model has been dealt with. Thus only an independent variable is included in the model, and the true values as well as the measurement errors are assumed to be distributed under normal distributions. In this case, the maximum likelihood estimates can be obtained by applying the explicit expressions shown in Ref. [4] according to the different assumptions that make the model identifiable. Nevertheless, multivariate models with more than one independent (and/or dependent) variable could be considered. Then, it could be possible that the maximum likelihood estimates did not have an explicit expression. Thus numerical methods to compute maximum likelihood estimates are needed. These numerical methods are implemented in several statistical packages. Among these packages, we would like to highlight the PROC CALIS of SAS®, the AMOS of SPSS®, the *sem* function for R,^[27] and the *Mplus*® package.^[28]

The estimation procedures introduced here are based on a frequentist point of view where the estimation process completely relies on the sample data. Alternatively, Bayesian approach^[29] has been proposed to get the structural equation model estimates. Using Bayesian approach the identification of the model can be achieved by introducing previous knowledge through the prior distributions of the parameters and hyperparameters involved in the model. The prior distributions combined with the likelihood lead to the parameter posterior distributions that are used for inferential purposes. With large sample size, both frequentist and Bayesian estimates concur because the likelihood has much more weight than the prior distributions on the posterior distribution. However, if the sample size is small the estimates are highly influenced by the prior belief and their consistency depends upon the appropriateness of the prior distributions. The structural equation model introduced here assumes that the relationship between the latent variables is unique for all individuals. This assumption can be quite unrealistic (Ref. [3], pp. 30) and as a consequence the estimates may be biased. However it can be relaxed by adding a random error to the structural equation that allows the relationship between latent variables randomly changes from one individual to other. Thus, the model is named the structural error-in-equation model (SEEM),^[4] which has been also applied to the individual bioequivalence problem.^[30]

The use of the structural equation model allows estimations of the underlying model that generates the data. When this model is applied to bioequivalence trials, the disaggregate nature of the approach allows us to determine why the formulations are not bioequivalent, rather than to decide if the formulations are bioequivalent. Therefore this approach can be understood as a tool to analyze what is wrong with a tested formulation.

Stuart–Maxwell Test

Jiang-Ming Johnny Wu

Biostatistics, DOV Pharmaceutical, Inc., Somerset, New Jersey, U.S.A.

Abstract

This entry discusses the Stuart–Maxwell test and its applications, and provides examples of clinical trials that implement the Stuart–Maxwell Test.

Keywords: Categorical data analysis, χ^2 -test; Contingency tables; Matched pairs; SAS macros.

INTRODUCTION

In clinical trials, categorical data analysis plays a crucial rule due to its broad applications that can be applied to different studies. There are many known test procedures that are used in categorical data analysis. For example, in the 2×2 independent samples cases: Pearson χ^2 -test of homogeneity, Fisher's exact test, likelihood ratio test, and Cochran–Mantel–Haenszel (CMH) test may be used. For 2×2 matched pairs case, the McNemar's χ^2 -test^[1,2] and the sign test, etc. can be used. Some of the test procedures mentioned in the 2×2 independent sample cases are still applicable for 3×3 and higher-order contingency tables. However, for 3×3 and higher-order matched pairs cases, only the Stuart–Maxwell test^[3,4] can be applied.

Due to the FDA requirements, it is well known that the SAS® language is the dominant software to be used for generating clinical tables, listings, and graphs in the pharmaceutical industry. However, there is no developed SAS procedure that can perform such a test. This lack of a developed SAS procedure creates a need for some pharmaceutical companies who use this test to perform the inferential analysis for their product in clinical trials. In this article, the author introduces this useful test and attempts to bridge this gap by developing an SAS® macro via SAS/IML®^[5] language to perform this test. The Stuart–Maxwell test will be presented and discussed in the second section. In the third section, a brief introduction regarding the use of the author's SAS macro is presented. A sample SAS main program that applies to an artificial data set is also included. In the fourth section, an application of the Stuart–Maxwell test with an example from the real-world clinical study using the developed SAS macro is presented. Finally, discussions regarding some special cases are included. The developed SAS macro codes that perform the Stuart–Maxwell χ^2 -test can be found in the paper by Wu.^[6]

THE STUART–MAXWELL TEST

This test deals with n matched pairs with r response categories with data configuration as shown in Table 1.

Here, a_{ij} is the number of pairs in the (i, j) th cell, $a_{i.}$ is the i th row sum, and $a_{.j}$ is the j th column sum, $i, j = 1, 2, \dots, r$. Also, the word “Group” is a generic term that may refer to a “Treatment” in clinical trials. Denote $p_i(p_{.j})$ to be the proportion of persons in group 2 who are in response category $i(j)$. Then the null hypothesis for the Stuart–Maxwell test can be formulated as follows:

$$H_0: p_{1.} = p_{.1}, p_{2.} = p_{.2}, \dots, p_{r.} = p_{.r}, r = 2, 3, 4, \dots \quad (1)$$

against the alternative hypothesis

$$H_1: p_{i.} \neq p_{.i} \text{ for at least one } i = 1, 2, \dots, r. \quad (2)$$

For the $r \times r$ table, the test statistic for testing $H_0: (p_{1.}, p_{2.}, \dots, p_{r.}) = (p_{.1}, p_{.2}, \dots, p_{.r})$ is

$$T = f' \mathbf{V}^{-1} f \approx \chi^2(r-1), \quad (3)$$

that is χ^2 distributed with $(r-1)$ degrees of freedom. Here,

$$f' = (a_{1.} - a_{.1}, a_{2.} - a_{.2}, \dots, a_{r.} - a_{.r}), \quad (4)$$

$$\mathbf{V} = [v_{ij}], \quad i, j = 1, 2, \dots, r-1, \quad (5)$$

$$v_{ii} = a_{i.} + a_{.i} - 2a_{ii}, \quad i = 1, 2, \dots, r-1, \quad (6)$$

$$v_{ij} = -(a_{ij} + a_{ji}), \quad \text{for } i \neq j, i, j = 1, 2, \dots, r-1, \quad (7)$$

and $\mathbf{V}^{-1}$ is the inverse matrix of $\mathbf{V}$.

Table 1 Data Configuration for the Stuart–Maxwell Test

		Group 1 Response category					Total
		1	2		r		
Group 2 Response category	1	a_{11}	a_{12}		a_{1r}		$a_{1.}$
	2	a_{21}	a_{22}		a_{2r}		$a_{2.}$
	...	...	...		...		
	r	a_{r1}	a_{r2}		a_{rr}		$a_{r.}$
Total		$a_{.1}$	$a_{.2}$		$a_{.r}$	$a_{..} = n$	

The only assumption for the Stuart–Maxwell test is that the data arise from a matched random sample with proportions $p_{.j}(p_{i.})$ for categories $1, 2, \dots, r$ for group 1(2). When $r = 2$ the Stuart–Maxwell test reduces to the well-known McNemar's test.^[1] Fleiss and Everitt^[7] has also shown that, when $r = 3$, the test statistic T can be reduced to the following format:

$$T = [\hat{a}_{23}(a_{1.} - a_{1.})^2 + \hat{a}_{13}(a_{2.} - a_{2.})^2 + \hat{a}_{12}(a_{3.} - a_{3.})^2] / [2(\hat{a}_{12}\hat{a}_{23} + \hat{a}_{12}\hat{a}_{13} + \hat{a}_{13}\hat{a}_{23})], \quad (8)$$

where

$$\hat{a}_{ij} = (a_{ij} + a_{ji}) / 2, \quad i, j = 1, 2, 3. \quad (9)$$

As usual, the decision rule for a α -level test is: reject H_0 if $T > \chi^2_{1-\alpha}(r-1)$.

In some situations a 3×3 table may be collapsed into a 2×2 table by combining two categories of response into one. In this case the McNemar's χ^2 -test can be used to perform the analysis. However, Fleiss^[8] suggested that under this case one should use a degree of freedom of 2, instead of 1.

The following is an example selected from Woolson's book:^[9]

Example

In a study of the psychological and social effects on the wives of myocardial infarction patients, a semistructured interview was conducted and tape-recorded on two occasions, 2 months after and 1 year after the husband's infarction. One item that was rated was the wife's degree of anxiety or distress. The data are as follows:

		At two months			
	Degrees of anxiety	None or mild	Moderate	Severe	Total
At one year	None or mild	20	30	10	60
	Moderate	5	10	5	20
	Severe	5	5	10	20
	Total	30	45	25	100

Determine whether there is sufficient evidence to conclude that the anxiety levels change from 2 months to 1 year.

Computations

From Eqs. 8 and 9,

$$\hat{a}_{12} = (30 + 5) / 2 = 17.5, \quad \hat{a}_{13} = (10 + 5) / 2 = 7.5, \\ \hat{a}_{23} = (5 + 5) / 2 = 5.$$

$$a_{1.} = 30, \quad a_{2.} = 45, \quad a_{3.} = 25, \quad a_{.1} = 60, \quad a_{.2} = 20, \quad a_{.3} = 20.$$

$$T = [5(60 - 30)^2 + 7.5(20 - 45)^2 + 17.5(20 - 25)^2] / [2(5 \times 17.5 + 17.5 \times 7.5 + 7.5 \times 5)] \\ = 9625 / 512.5 = 18.78.$$

$$H_0 : (p_1, p_2, p_3) = (p_{.1}, p_{.2}, p_{.3}) \text{ vs} \\ H_1 : (p_1, p_2, p_3) \neq (p_{.1}, p_{.2}, p_{.3}).$$

Because $\chi^2_{0.95}(2) = 5.99 < 18.78$, H_0 is rejected and in favor of H_1 . It is concluded that the wife's anxiety levels do change from 2 months to 1 year after husband's infarction.

THE SAS PROGRAM

A SAS[®] macro, written in SAS/IML[®] language, that performs the Stuart–Maxwell test has been developed by the author and can be found in the paper by Wu.^[6] To use that macro, one must do the following things to the data set.

- Rename the response variables as *yvar1* and *yvar2*.
- Sort the data set by visit number with final visit number equals to "99".
- Obtain the frequency distribution of the matched pairs (*yvar1*, *yvar2*) by visit number and store the results in an output data set with name "out".

The following is a sample SAS main program that uses the developed macro, STUART, with an artificial test data set.

Sample SAS Main Program

*** Sample main program to use the macro STUART ***;

```

  = 5 only ***;
%useit(visit = ); *** Example 2—Use the macro for all
  visits ***;
endsas;

```

THE APPLICATION TO CLINICAL TRIALS

The application of the Stuart–Maxwell test using the developed SAS macro, STUART, applied to a real-world clinical data set will be discussed in this section. The discussion begins with a brief description of the clinical study design and its purpose.

Clinical Study

The W. Company developed a Phase IV protocol to study its product, XXXXXXXX Silver-Coated Dressing that could cure “burn wounds.” The study design was a multicenter (10–15 centers), inpatient, matched-wound, randomized, open-label clinical trial. Patients with burn wounds were enrolled for treatment. Two large wounds of similar size on the body were selected from each patient and then both the study drug and the reference drug were randomly applied to these wounds. The planned sample size was 100 evaluable patients but eventually only 64 patients were obtained. The objective of the study was: To compare the safety, efficacy, cost effectiveness and quality of life benefits of XXXXXXXX silver-coated dressing to a standard burn treatment/dressing (silver sulfadiazine) in the treatment of partial-thickness burn wounds.

For the above clinical study the developed SAS macro, STUART, is applied to the data set to obtain the desired inferential analysis results. Two selected tables are presented below which include:

- **Table 2:** Analysis for reepithelialization for improved patients (ITT)
- **Table 3:** Analysis of physician’s evaluation of therapeutic response (ITT)

Here the reepithelialization includes four levels: light, moderate, marked, and completed. Also, the physician’s satisfaction includes four different levels: excellent, good, fair, and poor. It is seen that both responses are 4×4 matched pair cases and, because the study/reference drugs are

Table 2 Analysis of Reepithelialization for Improved Patients Intent-to-Treat Population

Reepithelialization	Counts (%)		Btwn-trt <i>p</i> -values ^a
	XXXXXXX (<i>N</i> = 61)	SSD (<i>N</i> = 61)	
Final day			
Light/mod. (1%–50%)	13 (21.3)	17 (27.9)	0.034 ^b
Marked (51%–99%)	15 (24.6)	14 (23.0)	
Completed (100%)	9 (14.8)	3 (4.9)	
Total	37 (60.7)	34 (55.7)	

Intent-to-treat population includes all subjects who had baseline and at least one post-baseline scores for primary efficacy assessments.

^a $p \leq 0.01$. $p \leq 0.001$.

^a p -values for categorical data were computed using Maxwell–Stuart χ^2 -test.

^b $p \leq 0.05$.

Table 3 Analysis of Physician's Evaluation of Therapeutic Response Intent-to-Treat Population

Satisfaction	Counts (%)		Btwn-trt p -values ^a
	XXXXXXX ($N = 61$)	SSD ($N = 61$)	
Final day			
Excellent	15 (24.6)	5 (8.2)	0.025 ^b
Good/fair	34 (55.7)	45 (73.8)	
Poor	10 (16.4)	9 (14.8)	
Total	59 (96.7)	59 (96.7)	

Intent-to-treat population includes all subjects who had baseline and at least one post-baseline scores for primary efficacy assessments.

^b $p \leq 0.01$. ^a $p \leq 0.001$.

^a p -Values for categorical data were computed using Maxwell–Stuart χ^2 -test.

^b $p \leq 0.05$.

applied to the same patients, the response variables are not independent. The results of using the Stuart–Maxwell test via the developed SAS macro are reproduced on the next page. Note that only the last page is displayed for Table 2. Also, both examples include two categories collapsed into one combined category, as can be seen in the results.

Both results show that the test drug has a significant effect (p -value = 0.034 and 0.025, respectively) over the reference drug, regarding “cure of the burn wounds” and “physician’s satisfaction.”

DISCUSSION

Because none of the references mentioned in this paper discussed what to do if the matrix $\mathbf{V}$ in Eq. 3 is singular (the matrix $\mathbf{V}^{-1}$ does not exist), it is worthwhile to have a raise this issue here. In the normal case, this test procedure is not applied if $\mathbf{V}^{-1}$ does not exist. However, because the clinical data usually is difficult to obtain and is expensive, we should utilize the clinical data as much as possible. Therefore, in order to utilize the data to the greatest extent, it is suggested to collapse the $r \times r$ table ($r \geq 3$) to be $(r-1)(r-1)$ by combining two categories into one new category, when zero rows and zero columns exist. To illustrate, consider the following example. Suppose $r = 3$ with 3 possible responses being: 1 = mild, 2 = moderate, and 3 = severe, and the matched pairs combination as shown in the following matrix.

$$\mathbf{A} = \begin{bmatrix} 5 & 0 & 10 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \quad (10)$$

If no collapsing category is done, then we will have:

$$f' = (10, 0) \text{ and } \mathbf{V} = \begin{bmatrix} 10 & 0 \\ 0 & 0 \end{bmatrix} \quad (11)$$

The usual analysis using Eq. 3 will result in $\mathbf{V}^{-1}$ does not exist and, hence, no conclusion will be reached. However, if

we combine category 1 and 2 as a new category, mild/moderate, for example, using the McNemar’s test will result in a test statistic $T = 10$ that will reject the null hypothesis. Examining the $\mathbf{A}$ matrix above, this appears to be a very fair conclusion.

The second suggestion is to always remember to use degrees of freedom ($r - 1$) when dealing with an $r \times r$ table, even if there are two response categories being combined into one category, as suggested by Fleiss^[8] for the $r = 3$ case.

In Wu,^[6] the proposed SAS macro will automatically search for zero rows and zero columns and combine them into one category, as long as at least one zero row and one zero column exist. To do this, a simple algorithm, described below, is used.

Algorithm to Find the Zero Row and Zero Column for the $\mathbf{A}$ Matrix

1. Find the number of zero rows (columns) and reduce the row (column) rank by one each time a zero row (column) is found.
2. Start with the smallest number of zero rows (columns) and remember its index, the i th row (column), $1 \leq i \leq r$, is zero and then try to find out whether the corresponding i th column (row) is zero or not.
3. If the corresponding i th column (row) is also zero, reduce the $\mathbf{A}$ matrix to be of dimension $(r-1)(r-1)$ by deleting both the i th zero row (column) and i th zero column (row).
4. If the corresponding i th column (row) is not zero, reduce the $\mathbf{A}$ matrix to the dimension $(r-1)(r-1)$ by deleting the i th zero row (column) and the first zero column (row) found.
5. When the $\mathbf{A}$ matrix contains only one zero row and one zero column, this row and column will automatically be deleted to form a new reduced matrix, $\mathbf{A}_3$, with a dimension of $(r-1)(r-1)$.

For the above example, the $\mathbf{A}$ matrix has one zero column (column 2) and two zero rows (row 2 and row 3).

Therefore, using the above algorithm, the macro will first identify column 2 to be deleted and then search for row 2 and determine whether it is a zero row. Because it is a zero row in this case, the macro then deletes row 2 to form a new reduced 2×2 matrix **A3** as follows:

$$\mathbf{A3} = \begin{bmatrix} 5 & 10 \\ 0 & 0 \end{bmatrix}. \quad (12)$$

Also, when such a reduction of matrix or combination of two categories into one has been performed, a warning message will automatically be displayed in the output file to warn the user that the interpretation of the table is different.

When the Stuart–Maxwell test is not applied, should the corresponding p -value always be assigned as missing? My personal opinion is no. For example, in the case where the matrix **A** is symmetric, it can be shown that the corresponding **V** matrix will always be singular and, therefore, the Stuart–Maxwell test will not be applied. However, in this case, a p -value of 1 makes much more sense than a missing p -value. A simple example is illustrated below for this purpose.

Let

$$\mathbf{A} = \begin{bmatrix} 1 & 2 & 0 \\ 2 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad (13)$$

then we have

$$f' = (0,0) \text{ and } \mathbf{V} = \begin{bmatrix} 4 & -4 \\ -4 & 4 \end{bmatrix} \quad (14)$$

that is singular. As a consequence, the Stuart–Maxwell test in Eq. 3 does not apply. However, the symmetry of the **A** matrix tells you that there is no difference between those matched pair responses and, therefore, a p -value of 1 is reasonable in this case.

Subgroup Analysis

Patricia B. Cerrito

University of Louisville, Louisville, Kentucky, U.S.A.

Abstract

Subgroup analysis can and should be performed when examining the results of both clinical trials and observational studies. This entry discusses the need for subgroup analysis and provides alternative methods of analysis and statistical examples of the benefits of this type of analysis.

INTRODUCTION

Because there are many different segments of the population as a whole and because these different subgroups of the population respond differently to treatment, subject recruitment for randomized, controlled trials is now actively attempting to be fairly representative of the population as a whole. However, this does not always occur.^[1] The statistical methods used need to investigate the outcomes for subgroups, in addition to the need to examine for statistical significance on the entire population. To do this, estimation and exploratory techniques need to be used. Validation by fresh data also needs to be emphasized.

NEED FOR SUBGROUP ANALYSIS

Most statistical hypotheses testing that occur in clinical trials make an assumption that the population is relatively homogeneous. This translates statistically into an assumption that the population has a distribution that resembles a bell-shaped curve (Fig. 1). However, consider the study^[2] that demonstrated that race and ethnicity are important in determining the absorption rates of drugs. Because body weight is also of concern, gender is also a real concern. In terms of trial outcomes, no distinctions are made to determine differences within the populations. This means that it is unlikely that the various symptoms and reactions will present themselves in the form of a bell-shaped curve. Phase I trials are designed to examine dosage levels for all subsequent trials. Typically they use small samples—samples too small to determine all differences related to race, gender, and ethnicity.

Consider a contrast to the assumption of homogeneity when heterogeneity exists in the population (Fig. 2). The assignment of “normal” is usually defined as the amount of the curve that contains 95% (or often 75%) of the area under the bell-shaped curve (Fig. 3). However, such an

assumption will overpresent one subgroup while underpresenting another. It can be seen clearly that half of the second peak falls above the established “norm.” This becomes even more noticeable when the distributions for the two subpopulations are graphed separately (Fig. 4). In fact, the assumption of normality in the presence of bimodality tends to redefine what is normal for one subgroup as an abnormal reaction, because it lies beyond the “norm” of the dominant subgroup (Fig. 5). In Fig. 5, the mean for the second group actually is placed at the upper limit for the first subgroup.

Thus a minority population could be misdiagnosed or treated improperly because of a reliance upon the assumption of homogeneity. Unfortunately, different subpopulations cannot always be clearly distinguished. Although gender, race, and ethnicity are fairly obvious indicators of subpopulations, other characteristics should also be considered. In this case, it is also a matter of finding out what subpopulations exist, as well as which ones should be investigated separately.

The use of subgroups by race or ethnicity is not without controversy. Ref. [3] strongly recommends that race and ethnicity be discarded as population subgroups, to be replaced by genetic markers. It states:

Studies using new technologies for understanding, measuring, and conceptualizing the sources of human variation reveal that approximately 85% of all variation in gene frequencies occurs within populations or races and only 15% variation occurs between such populations; there is no genetic basis for racial classification.

Contrast this statement with one made by Dr. Edward Sondik, Director for the National Center for Health Statistics: “Data showing racial differences in incidence and mortality have important scientific implications. These data should be looked at as offering clues for further research versus providing answers in and of itself.”

Fig. 4 Generalized representation of probability distributions for two homogeneous subpopulations showing the 70% upper tail norm established under the assumption that the entire population is homogeneous

Fig. 5 Generalized representation of two subpopulations demonstrating that one subpopulation can redefine the norms for a second subpopulation under the assumption of homogeneity

The first comment assumes that it is possible to collect data on the genetic makeup of clinical trial subjects; unless the trial itself examines genetic variation, this is not possible. The second statement provides a more realistic attitude in that statistical analysis does not examine why subgroups occur within the population; it only examines their occurrence. Although the claim is being made that race is a social construct and that it is not biological, the fact is that even a social construct determines existence.

ALTERNATIVE METHODS OF ANALYSIS

There are two nonparametric tools that can be used to estimate effects in a multimodal population. Both methods

are characterized by an ability to find subgroups as well as an ability to estimate the effects of treatment on those subgroups.

Mixing Distributions

As shown in Ref. [4], mixture models involve assuming that each observation x_j is taken from a superpopulation G , which is a mixture of a finite number of populations $G_1, \dots, G_g$ that occur in G in some proportions $\pi_1, \dots, \pi_g$, respectively, such that $\pi_1 + \dots + \pi_g = 1$. Then the density function for G is equal to:

$$f(x) = \sum_{i=1}^g \pi_i f_i(x)$$

where f_i is the density function of the population G_i . The function f then can only be found by estimating f_i for $i = 1, \dots, g$ as well as by estimating $\pi_1, \dots, \pi_g$. It is also sometimes necessary to determine the value of g —the number of populations involved. Therefore an attempt must be made to decompose f into its separate parts. The total number of populations g can be either known or unknown.

It is not possible to estimate if no sampling of G_i is done. However, it is also not possible to estimate f accurately. In fact, any attempt to estimate f without sampling from all components will result in severe bias. The largest of the populations tends to dominate the distribution. If the populations are of roughly equal size, both populations are misrepresented.

The advantage of using this method is that it is possible to determine just how many subpopulations should be considered and how many confounding factors should be used in making a diagnosis. Therefore it is possible to subdivide the population and to consider the extremes of symptoms for separate populations.

Kernel Density Estimation

Kernel density estimation uses data to develop an estimate of the population density function. For the collected data $\{X_1, \dots, X_n\}$, the estimate is given by the formula:

$$\hat{f}(x) = \frac{1}{na_n} \sum_{j=1}^n K\left(\frac{x - X_j}{a_n}\right)$$

where K is a known density function and a_n is a parameter that controls the degree of smoothness of f . As the value of a_n decreases, the number of peaks in the estimator increases. It becomes necessary to find an optimal value of a_n to determine the optimal number of peaks in the data. A method for doing this is discussed in Ref. [5]. This technique also gives a nice visual representation of the population distribution and enables the investigator to determine if

minority populations respond differently from the majority. However, this technique will also result in severe bias if the sample comes only from one segment of the population.

The tail probability can be estimated in the same way in which a cumulative distribution function can be estimated. As given in Ref. [5], this function can be defined as:

$$\hat{f}(u) = \frac{1}{na_n} \sum_{i=1}^n K\left(\frac{u - X_i}{a_n}\right)$$

where K is the cumulative distribution function of the kernel:

$$K(u) = \int_{-\infty}^u K(u) du$$

and $X_1, X_2, \dots, X_n$ is the collected sample. Thus the tails of the probability distribution can be determined in detail. The value u can also define a vector of random variables $u = (x, y, z, t)$. Then $f(u)$ is modified to equal (for the discrete variable y):

$$\begin{aligned} \hat{f}(x, y, z, t) &= \frac{1}{na_n^3} \sum_{j=-\infty}^{\infty} W(\hat{S}_n, i, j) \\ &\times \sum_{l \in C_n(j)} k\left(\frac{x - X_l}{a_n}, \frac{z - Z_l}{a_n}, \frac{t - T_l}{a_n}\right) \end{aligned}$$

PROBLEMS WITH SUBGROUP ANALYSIS

Finding Significance Where None Exists

There is a saying among statisticians that if you torture the data, they will confess. This is particularly true of subgroup analysis and retrospective studies. Therefore any results from these types of analysis can be only preliminary, not conclusive. This falls under the general topic of data mining.^[6] Although a data mining procedure can be used to identify a model or a variable of interest, only fresh data can be used to verify the significance of the model. The need for verification is clearly stated:^[7]

The difficulties associated with direct reliance on data in a whole series are exacerbated if one attempts to pick out subclasses marked by strikingly good or bad results. The idea seems reasonable enough, but it ignores a somewhat subtle, inescapable fact: one can always expect to find some good-looking and some bad-looking subsets in any body of data, even when no bias has influenced any part of it. Furthermore, such differences among subsets can easily be large enough to look quite convincing to the unsophisticated analyst.

The pitfalls of subgroup analysis were very vividly presented by the ISIS-2 trial, where a statistically significant subgroup result on the prevention of fatal heart attack by ingesting aspirin was obtained by classifying subjects by astrological sign.^[8]

One way to avoid this problem is to preplan a small number of subgroup analyses by stratifying the data in the protocol. A second way is to perform the primary assessment to demonstrate statistical significance before investigating any subgroups for significance. As stated in Ref. [7]: “[P]ost-hoc subgroup results should be viewed as hypothesis-generating rather than proof.” Unfortunately, published results do not generally indicate how many subgroup analyses were actually performed. The main way to avoid the problem is to regard any results of subgroup analysis as hypothesis-generating, to be validated by the collection of a fresh data set to see if the results still hold.

Two recent papers^[9,10] rely very heavily on subgroup analysis. In Ref. [9], no significant difference was found between treatment groups. Therefore the significant difference found for subjects age 60 years and younger should definitely be regarded as a hypothesis generated, with a need for verification by additional data collection. The paper went on to examine subgroups of the subgroup, all of which were highly significant. As discussed in Ref. [7]: “[I]f n subjects are divided at random into k equal-sized subgroups, then the difference between the largest and the smallest subgroup means has an expected value that is approximately k times the standard error of the mean of the whole group.” This alone demonstrates that such high P values are to be expected. Although the paper does discuss the problem of subgroup analysis and the care taken to ensure that the results were not spurious, the choice of the age of 60 years was made because this was the optimal value to find statistical significance.

In Ref. [10], the difference between treatment and control groups was not significant. As stated, “[A] retrospective survival analysis was performed in patient subsets that showed favorable responses to VMO treatment in the first interim analysis.” It is clear that subgroups were chosen after the fact. Any difference in survival found retrospectively has to be tested with preplanned stratification before the result is considered valid. This paper does not discuss the problems of subgroup analysis. The paper does indicate that the study is not definitive and should be done with sufficient numbers of patients in all subgroups.

The problem of these types of subgroup analyses is clearly examined:^[11]

The controversy began with the retrospective analysis of results by age subgroups, a method of evaluation unanticipated in the design of all but one of the trials; these trials were planned with marginal power that was sufficient only for the whole-group examination of the data. When used to interpret the end results of the trials, retrospective

subgroup analysis reduces the power of the results and thus substantially increases the likelihood that an observed benefit will not achieve statistical significance... [P]ost hoc data-dredging for subgroups of patients or subsets of events, however qualitatively dramatic their results, should only generate hypotheses for the next trial, not conclusions from this one.

Thus subgroup analysis can create controversies within the medical community by stating conclusions that are only generated hypotheses. Further studies, often not performed, are needed to make the conjecture conclusive.

Because few people actually understand the statistical complications in the use of subgroup analysis, these should be recognized in any paper discussing a study where subgroup analysis was performed.

Insufficient Power

Before the data for any test are collected, there are four different parameters that must be considered:^[12]

Type I (or α) error.
Type II (or β) error.
Effect size.
Sample size.

These four variables are closely related, so three are specified by the investigator and the fourth is computed as a function of the other three.

Type I Error

The purpose of any statistical hypothesis test is to make an inference about a population by using a relatively small sample. The possibility of error always exists. Because it cannot be eliminated, it should be controlled. Type I error is defined to be the probability of being wrong if the investigator rejects H_0 . Typically, $\alpha = 0.05$ is considered significant and $\alpha = 0.01$ is considered highly significant. Then the hypothesis test is stated:

H_0 : treatment is not effective.
 H_1 : treatment is effective.

Type II Error

More importantly, type II error should also be considered, although it is usually ignored. Type II error is defined to be the probability of being wrong if the investigator accepts H_0 . Unfortunately, if the α error is low, the β error can be quite high. Therefore consider the question posed earlier:

H_0 : treatment is not effective.
 H_1 : treatment is effective.

If the value of β is not computed, then it is not possible to decide whether to accept H_0 . Therefore the best that can be decided is whether to reject H_0 or to fail to reject H_0 . Failing to reject H_0 is often assumed as equivalent to accepting H_0 , although it is not. In fact, independent of the size of the sample, the maximum possible β error is always $1 - \alpha$. Thus if $\alpha = 0.05$, it is possible to have a β error of 0.95. Only by defining an effect size can α and β be reduced simultaneously.

In statistical terminology, the power of the test is defined to be $1 - \beta$. Typically, in a medical study, α is considered acceptable at 0.05 and β is acceptable at a level of 0.20. In this case, the power of the test is stated as 80%. However, when subgroup analysis is performed, it is performed with only a subset of the data. In this case, the result will be of low power, and it will not be possible to conclude that the subgroup reacts differently than the rest of the population.

Effect Size

If a new treatment increases patient survival by 1 day, does it provide sufficient improvement to be worthwhile? Statistical significance cannot determine whether the size of the difference is important—that question must be answered by the investigator. The effect size is defined to be the point at which the difference between treatments becomes important. Once the effect size is defined, the hypothesis can be rewritten (when limited to two treatments):

$$\begin{aligned} H_0: u_1 &= u_2 \\ H_1: u_1 - u_2 &> u' \text{ or } u_2 - u_1 > u' \end{aligned}$$

where u' is the effect size. Once a specified effect size is given, a sample size can be computed so that both the α and β errors remain small.

Sample Size

The smaller the effect size, the larger the needed sample size to keep both α and β under control. If the effect size is too small, it is possible that the required sample size is too large for an experiment to be conducted, except for prohibitive cost. On the other hand, if the sample size is limited by cost, then the effect size may be so large that H_0 can be rejected only in such extreme situations that it would be virtually obvious without any statistical analysis.

Therefore effect size is usually identified as a percentage of the population variability, with the corresponding sample size computed for small, medium, and large effect sizes. Once this has been done, the null hypothesis can be either accepted or rejected, depending upon the outcome of the collected data.

If the effect size is not considered prior to the start of an experiment, it is often the case that the effect size is so large as to render the experiment meaningless. For example, in a study of 71 randomized trials, it was found that

50 of them had less than 90% power of detecting a 50% improvement. Thus if a surgical procedure were to result in the survival of 50% or fewer of the patients, the hypothesis test would not detect this as statistically significant.^[7]

The main statistical techniques used to avoid the problem of small sample size is the use of meta-analysis. The results from different studies are combined to increase the power so that the conclusions will be definitive. However, when the results from meta-analyses were compared to the results of subsequent large trials, it was found that they differed over 30% of the time. Another method more recently employed has been to set up national depositories.^[13] Data from all parts of the country are collected to be examined. The data lack quality control and randomization and so the results must be viewed as tentative. A test for equivalency remains a serious problem. The best solution might be to make the test on the overall population and then to examine various subpopulations by estimating outcomes rather than using inferential techniques.

EXAMPLES FROM THE MEDICAL LITERATURE

Comparison of Subgroups Within the Population

Ref. [14] examined a subgroup of the general population, sampling 127 African Americans. They were divided into two experimental groups and one control group. Of the 127, 16 were lost to follow-up. Using a 5% level of significance and 80% power, this sample of 111 is sufficient to detect a difference of 20% between groups.^[12]

Identification of Subgroups to Investigate

These studies are generally conducted retrospectively. Subgroups are identified and tested simultaneously. The results of such studies cannot be conclusive; all must be examined by using fresh data. Ref. [15] provides a classic example of subgroup analysis. There were 1395 patients originally recruited into the study. Of the initial sample, 262 patients were identified as having mild to moderate congestive heart failure. This subgroup of patients was followed for 1 year. Using power analysis for log-rank statistics, with a 5% significance level and 80% power, this patient sample is sufficiently large to detect a 15% difference in mortality.^[16]

This is in contrast to Ref. [17], which examined the relationship between aspirin and enalapril by retrospectively adding a variable to the analysis. Although the title indicates that this is a subgroup analysis, the analysis was conducted over the entire patient base.

The hypothesis generation of subgroup analysis is clearly demonstrated in Ref. [18]. As stated in the paper:

After the minimum hematocrit during cardiopulmonary bypass had been determined to be an independent risk

factor for mortality, it was necessary to perform a cutoff point analysis to establish a specific hematocrit level at which there is a statistically significant difference in post-operative mortality. The cutoff point analysis was achieved by dividing the entire patient population into dichotomous groups using different minimum hematocrit levels during cardiopulmonary bypass as a cutoff point. All of these different variables were then entered into a multiple logistic regression model that contained the other statistically significant preoperative risk factors for risk adjustment. This cutoff point analysis is able to pinpoint a specific hematocrit level at which there is a statistically significant difference in mortality after adjusting for other preoperative risk factors.

After a specific hematocrit level was determined to be statistically significant for mortality, a subgroup analysis was then performed to distinguish the difference between high-risk and low-risk populations. This subgroup analysis was performed by dividing the entire patient population into high-risk and low-risk subgroups. The high-risk population consists of patients with at least one statistically significant preoperative risk factor for mortality, and the low-risk population consists of patients without any statistically significant risk factors for mortality. Minimum hematocrit level achieved during cardiopulmonary bypass was again examined as an independent risk factor for mortality in each of the subgroups. Cutoff point analysis was again performed.

Cutpoint analysis as just discussed is an attempt to find the optimal hypothesis. Unfortunately, the study did not yield a conclusive result by testing an additional set of subjects. Therefore any conclusions in the paper must be tentative.

All three of these examples have to deal with the issues of finding significant subgroups where none exists. All should be regarded as conjectures in need of validation.

Mammography Screening

One of the more controversial of the subgroup analyses deals with the mammography screening of women ages 40–49 years. The major studies conducted were not specifically designed to address the question; a cutpoint was

considered at age 50 years. Consider two such studies^[19] (Table 1). Note first the extremely large number of observations in both studies compared to the small number of deaths. A subgroup analysis reduces the number of deaths still further. The HIP study did find a significant difference in mortality for women ages 40–49 years, demonstrating a benefit to mammography; the SNB study did not. As a result of these studies, Ref. [20] made the following conclusion:

Decisions must be made concerning the diversion of resources that would be required to implement mass screening for breast cancer. On the positive side of the balance sheet, there is a marginal reduction in deaths from breast cancer in older women. On the negative side are the financial cost and the induced morbidity. Negative factors also include the false-positive results leading to unnecessary operations, the false-negative results that lead to inappropriate reassurance, the raised level of anxiety in the female population, and the tiny but real risk of radiation-induced cancers.

The calculations presented in this study, with only inappropriate surgical intervention used as the index of harm, demonstrate a harm/benefit ratio of between 21:1 and 62:1. Enough data are now available to suggest that the American Cancer Society recommendations should be ignored in view of the net harm caused by screening for breast cancer.

Contrast this conclusion with the one given in Ref. [21]:

The scientific limitations of retrospective subgroup analysis notwithstanding, results show consistent point estimates of mortality reduction in women who are screened compared with controls for women aged 50 and older (average mortality reduction of approximately 30%; statistically significant mortality reduction in several individual trials), probably because of the much larger number of older women in the trials. For women aged 40 to 49 years, most point estimates show mortality reductions ranging from 22% to 49%, but three trials show no benefit and none of the trials individually shows statistically significant results.

Table 1 Results of Two Major Mammography Studies

Value	HIP 10-year mortality study		SNB 7-year mortality study	
	Number	Percent	Number	Percent
<i>Death from breast cancer</i>				
Number of women screened	31,888	100	78,085	100
Screened	146	0.458	87	0.111
Control	192	0.602	125	0.160
Reduction in death from breast cancer	46 (24% relative)	0.144	38 (30% relative)	0.049
<i>Death from all causes</i>				
Screened	2,235	7.009	4,846	6.206
Control	2,116	6.636	4,787	6.131
Increase in death from all causes	119 (6% relative)	0.373	59 (1% relative)	0.076

HIP = Health Insurance Plan of New York; SNB = Swedish National Board of Health and Welfare.

Table 2 Meta-Analysis of Mammography Studies

Trial	Years of follow-up	Study group deaths	Study group person-years	Control group deaths	Control group person-years	Relative mortality	95% confidence interval
Two-country	15	45	264,059	39	207,725	0.91	0.59–1.39
Malmö	15	15	61,000	23	62,000	0.66	0.34–1.27
Stockholm	12	25	173,866	12	87,826	1.05	0.53–2.09
Gothenburg	10	19	106,000	37	129,000	0.62	0.36–1.08
Edinburgh	10	25	97,206	31	88,766	0.73	0.43–1.25
HIP	18	49	248,454	65	253,085	0.77	0.53–1.11
NBSS	10	73	252,060	66	251,814	1.10	0.78–1.54
Turku	7	3	48,068	9	41,532	0.29	0.07–1.08

Thousands of lives are probably lost each year because women are not being screened. We believe that it is much more prudent to endorse mammographic screening now, risking the unlikely subsequent determination that the effort was ineffective, than to withhold screening until it is determined whether “proof” of efficacy will be obtained, risking the loss of so many lives.

A meta-analysis was performed on the eight major studies of mammography^[22] (Table 2). The study concludes:

The decision whether or not to screen this age group will depend on subjective views of the importance of the benefit and the ability to provide the resources involved. It seems clear, however, that while the size and timing of the mortality reduction require further research, the existence of such a reduction is no longer in question.

This confirms the result of a similar meta-analysis.^[23]

CONCLUSION

Subgroup analysis can and should be performed when examining the results of both clinical trials and observational studies. Some of the subgroups within the population are obvious and should be collected in the course of the study; however, others are more subtle and often are examined because of the trial outcomes. Because subgroup analysis can suffer from lack of statistical power and also from too many subgroup investigations, the results should be considered tentative pending further studies. These studies can take the form of large trials with sufficient power to be conclusive or of meta-analysis. Meta-analysis and large trials disagree in outcome approximately 30% of the time. Risks, benefits, and costs should all be examined when taking the outcomes of subgroup analysis to apply to clinical practice.

Subject-Treatment Interaction

Gary L. Gadbury

Department of Statistics, Kansas State University, Manhattan, Kansas, U.S.A.

Abstract

The focus of this entry is subject-treatment interaction as a variability in the magnitude of true individual effects of a treatment and, when such variability is large, a practical consequence may be that the effect of treatment for some individuals has important differences from the average effect.

Keywords: Causation; Clinical trials; Individual effects; Potential outcomes; Treatment heterogeneity.

INTRODUCTION

That the effect of a treatment will vary among subjects is not surprising, nor is it a recent concept. Roses^[1] provided an 1892 quote by Sir William Osler, “If it were not for the great variability among individuals medicine might as well be a science and not an art.” Subject-treatment (S-T) interaction is, as the term implies, an interaction of specific subjects with applied treatment(s). The result of such interaction is a variability of “individual treatment effects” or “individual treatment heterogeneity” in a population of interest. Effects of treatment may be assessed as a measurement of efficacy or toxicity because variability in either may have important consequences. Although such variability has often been acknowledged as an important consideration, medicine today generally makes use of statistical information gathered about the general population (often about the “average” subject) and then applies it to the individual.^[2] One exception is the interest in individual bioequivalence for drug “switchability” (cf., Ref. [3]) where effects of subject by formulation interaction are investigated, typically in crossover designs (e.g., Refs. [4–6]). S-T interaction in a crossover design is a topic considered in a later section.

When there is a high degree of S-T interaction in a population, there may be a nonnegligible proportion of the population responding differently to a treatment, and possibly in the opposite direction, from the average subject. Even within a carefully designed clinical trial, the validity of results may be compromised if there is a wide variability of individual treatment effects, prompting at least one author to suggest that inference about the mean treatment effect be supplemented with information about suspected variability of effects.^[7] Variability in magnitude has been called a noncrossover interaction as long as the direction of the effect is the same across subjects, and variation in direction of individual effects has been termed a

crossover interaction.^[8] The latter is usually of more concern to researchers, possibly playing a role in adverse drug reactions.^[9]

Advances in the field of pharmacogenomics have raised hopes that genetic information may be used to identify subjects who will “succeed” with a specific treatment.^[10] Recent high-throughput technologies such as microarrays have enhanced the ability to search for such genetic contributors.^[11,12] Gene-treatment interactions are only one component of S-T interaction. Other components may relate to sex, age, environment, other medications, etc.,^[13,14] thus S-T interaction is an upper bound for gene-treatment interactions.^[15] How much S-T interaction is explained by gene-treatment interactions is a nontrivial problem as clinical studies are often not designed to evaluate S-T interaction.^[15]

The degree of S-T interaction in a population can be quantified by a parameter that is related to the variance of individual treatment effects, although this parameter cannot be directly estimated using observable data.^[16] Sometimes a comparison between a proportion of subjects benefiting on a new treatment and the proportion benefiting on a standard treatment is interpreted as being related to the probability that an individual subject will benefit on the new treatment. This is not quite true. Even with crossover trials, identification of S-T interaction depends on how one defines a “true individual treatment effect.” However, S-T interaction can produce effects that are testable using such data. Methods to detect these effects have focused on identifying subsets or covariates to explain perceived treatment heterogeneity.^[8,17–20]

Kent and Hayward^[21] comment that “baseline risk” across subjects in a study may be highly skewed, thus nearly ensuring that the summary results (e.g., estimates of average effects) will be different from the typical patient. They, as well as Kent et al.,^[22] suggest that baseline risk and competing risk heterogeneity may explain treatment

effect heterogeneity, and stratifying on metrics derived from these risks can enhance detection of subgroups that respond differently to treatments. They propose a risk stratified analysis (versus a conventional subgroup analysis) for detecting important differences in treatment effects, and stress the importance of understanding the complex relationship among baseline risk, treatment related harm, and competing risk when making good individual-patient recommendations and decisions.

One method to detect the presence of S-T interaction is to examine the proportion of similar responses between the treatment outcome (say, X) and the control outcome (say, Y). This overlap has been called the proportion of similar responses (PSR).^[23] Given two density functions $f(x)$ and $g(x)$, the PSR is defined as the area under the smaller of the two population density functions and is expressed as

$$PSR(f, g) = \int \min(f(x), g(x)) dx.$$

Stine and Heyse^[24] have developed a non-parametric estimate of the PSR by using kernel density estimators to estimate both $f(x)$ and $g(x)$. Note that the kernel density estimates are made on the marginal densities of the two outcome variables without consideration of the joint distribution. As such, the value of the (non-estimable) correlation parameter, ρ_{xy} , cannot be included in the calculation of the PSR. Whether the marginal distributions and, thus, the degree of overlap between them (i.e., PSR) applies to the population of interest is another matter because patients in clinical trials are often not representative of the target populations.^[25] The issue of sample selection in a clinical study is not directly considered herein, nor are the various issues that arise in clinical trials such as compliance and dropout that pose challenges for even estimating average effects (c.f., Ref. [26]).

OVERVIEW

The focus of this entry is S-T interaction as a variability in the magnitude of true individual effects of a treatment and, when such variability is large, a practical consequence may be that the effect of treatment for some individuals has important differences from the average effect. This focus is consistent with that used in earlier papers.^[16,27-9] The goals of the entry are the following: Define a true individual treatment effect; quantify S-T interaction as a nonestimable population parameter; quantify the probability that an “individual” will experience an “unfavorable” effect of treatment and show that this probability is a function of S-T interaction (hence also nonestimable); show some connections between S-T interaction and causation; demonstrate what can and cannot be learned about S-T interaction using observable data; and finally, suggest design modifications or extensions that may facilitate a more precise evaluation

of the magnitude of S-T interaction (herein, “nonestimable” means that observable data contain insufficient information to allow direct estimation of a parameter). Details will be provided for a two-sample completely randomized design; however, some discussion is included later for matched-pairs and crossover designs. It is hoped that the entry will at least alert the researcher to the assumptions that must be made when equating variability of “perceived” individual treatment effects with variability of true individual effects.

COMPLETELY RANDOMIZED DESIGN COMPARING TWO TREATMENTS

Individual Treatment Effects and Potential Outcomes

Suppose two treatments, T and C , are being compared in a two-sample completely randomized design. Further, suppose that at a particular point in time, the value of an outcome variable, Y , will be measured. This outcome may be a change from baseline, and it may be quantitative or dichotomous (i.e., success or failure). For a subject receiving treatment T , the outcome $Y^{(T)}$ is observable, and for a subject receiving treatment C the outcome $Y^{(C)}$ is observable. The bivariate pair $[Y^{(T)}, Y^{(C)}]$ are potential outcomes^[30,31] in that only one of the two is observable for a specific subject at a particular time.

To avoid the need for the superscripts and thus later simplifying notation, hereafter X is the outcome to treatment T and Y is the outcome to treatment C . The bivariate pair (X, Y) are potential outcomes, and the variable $D = X - Y$ defines a true individual treatment effect. Although D cannot be observed for any subject, its definition helps to conceptualize what is meant by a true individual effect and thus clarify what can and cannot be learned about these effects using observable data. The potential outcomes framework has found use in the area of statistical causality because the ultimate interest in causal inference is effects of causes (i.e., treatments) on specific subjects. (p. 947)^[32] The “fundamental problem of causal inference” is that only one of the two potential outcomes, X or Y , can be observed for an individual subject.^[32] One can imagine a study evaluating k treatments, and the potential outcomes would be a vector containing k outcomes (rather than two); only one of the k outcomes would be observable for a given subject at a particular time.

It is the average treatment effect, $E(D)$, that is usually of interest but it is the variance, $\text{Var}(D)$, that quantifies the degree of variability of individual treatment effects and hence the magnitude of S-T interaction. S-T interaction is present when $\text{Var}(D) > 0$, but this quantity cannot be directly estimated using observed data because of the fundamental problem of causal inference mentioned earlier; however, bounds for it can be derived and these can be estimated.

A Model for Continuous Outcomes and Consequences of S-T Interaction

Consider N subjects in a two-sample design and the variables X and Y represent outcomes to treatments T and C , respectively. The set of N potential outcomes has the form given below (left) that, after treatment assignment produces observed outcomes of the form shown (right), and where the “?” represents an unobservable potential outcome.

$$\begin{pmatrix} X_1 & Y_1 \\ \vdots & \vdots \\ X_N & Y_N \end{pmatrix} \xrightarrow{\text{Treatment Assignment}} \begin{pmatrix} X_1 & ? \\ ? & Y_2 \\ \vdots & \vdots \\ ? & Y_{N-1} \\ X_N & ? \end{pmatrix} \quad (1)$$

An assumption is needed that a subject's outcome will be unaffected by the treatment assignment outcome for other subjects in the study. This was termed no interference between units^[33] and generalized later as a stable unit treatment value assumption (SUTVA).^[34]

One could define a treatment indicator variable and develop an estimate of $E(D)$ and its standard error with respect to a finite population randomization distribution.^[28,35] Here we will suppose an infinite population model, and potential outcomes (X_i, Y_i) , $i = 1, \dots, N$ are a random sample from a bivariate normal distribution with mean vector (μ_x, μ_y) , variances, σ_x^2 and σ_y^2 , and correlation ρ_{xy} . Selection bias associated with a nonprobabilistic recruitment process are beyond the scope of this entry and is discussed elsewhere.^[36] After a random treatment assignment, we have the usual two-group parallel design and a mean treatment effect, $\mu_D = \mu_x - \mu_y$, and standard error are easily estimated using observed data because they are functions of parameters in the marginal distributions of X and of Y . The quantity for S-T interaction, $\sigma_D^2 = \text{Var}(D) = \text{Var}(X - Y)$, cannot be directly estimated because $\sigma_D^2 = \sigma_x^2 + \sigma_y^2 - 2\sigma_x\sigma_y\rho_{xy}$ and there is no available information about ρ_{xy} in observable data; that is, it is nonestimable.

One can write σ_D^2 as follows:

$$\sigma_D^2 = (\sigma_x - \sigma_y)^2 + 2\sigma_x\sigma_y(1 - \rho_{xy}) \quad (2)$$

So there is S-T interaction present unless $\sigma_x = \sigma_y$ and $\rho_{xy} = 1$, and the former condition can be tested using observed data but the latter cannot. Whether or not S-T interaction produces unfavorable consequences on a subset of the population depends upon how large σ_D is with respect to μ_D , a quantity that depends on ρ_{xy} . As an illustration, assume $\sigma_x = \sigma_y = \sigma$, that there are n subjects in each of two treatment groups (so $N = 2n$), and that a positive μ_D above some threshold is a “beneficial average treatment effect” (without loss of generality, assume this threshold is zero). Letting $\tau = \mu_D/\sigma_D$, the power to detect a positive average treatment

effect is $\text{Power} = 1 - T(t_{1-\alpha}, 2n-2, \tau\sqrt{n/2})$, where $T(t_0, k, \lambda)$ is a cumulative distribution function of a noncentral t random variable with k degrees of freedom and noncentrality parameter λ , evaluated at t_0 . The proportion of the population experiencing a negative effect of treatment T with respect to C is $P_- = P(D < 0) = \Phi(-\tau/\sqrt{2(1-\rho_{xy})})$. Fig. 1 shows the relationship between particular ranges of τ (top horizontal axis), P_- (bottom horizontal axis), and Power (vertical axis) when the nonestimable $\rho_{xy} = 0.7$. For example, one may have high power (>80%) to detect a positive average treatment effect when more than 10% of the population experience a negative effect, unless μ_D is 1.3 times larger than σ when $n = 20$. The issue is more pronounced for larger sample sizes and for smaller values of ρ_{xy} .

In practice, one will not know the true value of ρ_{xy} and, so, will be unable to directly evaluate the size of σ_D with respect to μ_D . Little else can be done with observable data except to note that letting $\rho_{xy} = 1$ and -1 produces bounds for σ_D^2 that can be estimated.^[16] In a data example, Gadbury, Iyer, and Allison^[27] assessed the sensitivity of estimated σ_D^2 and its consequence, $P(D < 0)$, to a range of values for ρ_{xy} using maximum likelihood estimation. Sampling variability was assessed using large sample properties of maximum likelihood estimators (MLEs) and also using a bootstrap technique for smaller samples.

A Model for Binary Outcomes and Consequences of S-T Interaction

Gadbury, Iyer, and Albert^[29] showed the following multinomial population model for binary potential outcomes:

$$\begin{array}{ccccc} (x, y) & (0, 0) & (0, 1) & (1, 0) & (1, 1) \\ P(X = x, Y = y) & \pi_1 & \pi_2 & \pi_3 & \pi_4 \end{array} \quad (3)$$

Fig. 1 Consequences of S-T interaction in a bivariate population when $\sigma_x = \sigma_y = \sigma$, $\tau = \mu_D/\sigma$ and $\rho_{xy} = 0.7$. There are n subjects in each of the two treatment groups

where $\sum_i \pi_i = 1$. Suppose that an outcome equal to 1 is a success and 0, a failure (such outcomes may also reflect a collapsing of continuous outcomes into two categories, improvement from baseline or no improvement). At a particular time, treatment T is a success with respect to C for a proportion π_3 , and $D = 1$ for these subjects. However, treatment C is superior to T for a proportion π_2 , and $D = -1$ for this subset. There is no difference, $D = 0$, for a proportion $\pi_1 + \pi_4$. S-T interaction is present in the population unless one of the three quantities is equal to 1: π_3 , π_2 , or $\pi_1 + \pi_4$. However, the individual parameters π_i , $i = 1, \dots, 4$ are nonestimable in observable data and only parameters in the marginal distributions can be estimated. The mean treatment effect is $E(D) = E(X - Y) = \pi_3 - \pi_2$ and it is this quantity that is estimated in the usual comparison of two population proportions. Suppose $E(D) = 0.4$, then it could be that $\pi_3 = 0.4$ and $\pi_2 = 0.0$, or $\pi_3 = 0.7$ and $\pi_2 = 0.3$. In the latter case, 30% of the population would be better off with treatment C although treatment T was superior on average. With no additional information, the most that can be done is to bound the individual parameters with quantities that can be estimated.^[29] For example, estimable bounds for π_2 are given by the following inequalities:^[29]

$$\max(0, \pi_2 - \pi_3) \leq \pi_2 \leq \min\{1 - (\pi_3 + \pi_4), \pi_2 + \pi_4\} \quad (4)$$

The Role of a Covariate

Suppose that a covariate, Z , is observable for all subjects in a study and that Z is unaffected by treatment. Examples are a subject's age, baseline outcome, gender, or a particular genotype. Assume that, as before, two treatments are being compared and either X or Y is observed for a subject depending on treatment assignment outcome. A well-known role for Z is to improve the efficiency in estimating a mean treatment effect. It can also be used to refine the estimable bounds for σ_D^2 .

Suppose that (X, Y, Z) is a trivariate normal random variable and let β_{XZ} and β_{YZ} be the population regression coefficients relating Z to X and to Y , respectively. Let $\sigma_{X|Z}$ and $\sigma_{Y|Z}$ be the standard deviations of the conditional distributions of X and of Y , respectively, given Z , let $\rho_{XY|Z}$ be the partial correlation between X and Y given Z , and σ_Z^2 be the variance of the marginal distribution of Z . Then the following can be shown.

$$\sigma_D^2 = (\sigma_{X|Z} - \sigma_{Y|Z})^2 + (\beta_{XZ} - \beta_{YZ})^2 \sigma_Z^2 + 2\sigma_{X|Z}\sigma_{Y|Z}(1 - \rho_{XY|Z}) \quad (5)$$

Several points can be made regarding Eq. 5. First, all parameters in Eq. 5 can be estimated using observed data except the partial correlation. Second, if Z is a perfect linear predictor of X and of Y , then all S-T interaction is explained by a covariate-treatment interaction as $\sigma_{X|Z} = \sigma_{Y|Z} = 0$. Third, if this is not the case, then $\sigma_D^2 = 0$ if

and only if $\sigma_{X|Z} = \sigma_{Y|Z}$, $\beta_{XZ} = \beta_{YZ}$, and $\rho_{XY|Z} = 1$, and the last equality cannot be tested using observed data. Fourth, letting $\rho_{XY|Z} = -1$ and 1 results in upper and lower bounds for σ_D^2 that can be estimated. Interestingly, these bounds are exactly those that result from the positive definiteness requirement of the three-dimensional correlation matrix for (X, Y, Z) .^[16] Gadbury and Iyer^[16] developed MLEs for these bounds and derived their large sample properties. Gadbury, Iyer, and Allison^[27] showed an example where data suggested a covariate by treatment interaction (i.e., $\beta_{XZ} \neq \beta_{YZ}$) and that subjects with higher baseline blood pressure appeared to have larger decreases in blood pressure after 12 weeks on a calcium supplement vs. the placebo group. They noted that although some S-T interaction is explained by $\beta_{XZ} \neq \beta_{YZ}$, there can remain individual treatment heterogeneity in subpopulations defined by values of the covariate Z . Conditioning on a value of Z , similar results for the two-sample problem (without the covariate) can now be applied to the conditional bivariate distribution of X and Y given $Z = z$, where the mean treatment effect is $\mu_{D|Z=z} = \mu_X - \mu_Y + (\beta_{XZ} - \beta_{YZ})(z - \mu_Z)$ and the conditional variance of D is $\sigma_{D|Z}^2 = \sigma_{X|Z}^2 + \sigma_{Y|Z}^2 - 2\sigma_{X|Z}\sigma_{Y|Z}\rho_{XY|Z}$. Gadbury, Iyer, and Allison^[27] then, for varying $\rho_{XY|Z}$ between -1 and 1, assessed the sensitivity of MLEs for $\sigma_{D|Z}$ and associated MLEs for the probability of a negative treatment effect for a subpopulation of subjects defined by a value of $Z = z$, i.e., $P(D < 0 | Z = z)$. Large sample properties of MLEs were used to compute confidence intervals.

Working out the details of using Z as a predictor for binary outcomes and the associated refinement of bounds for π_2 is a subject for future work. Another use for Z , or any other subjective information regarding the subjects in a study, is to use this information to match subjects into pairs. Some discussion of this situation is given in the next section along with discussion of the two-period crossover design.

INDIVIDUAL TREATMENT EFFECTS IN TWO OTHER DESIGNS

Matched-pairs designs allow for observation of a treatment effect for a pair and computation of the variance of paired differences. Whether the paired differences equal true effects for individuals depends on the quality of the matching criteria. Crossover designs allow for a treatment effect to be observed for each individual because each individual receives each of the two treatments separated by a washout period. The next two subsections define individual effects and S-T interaction for these two types of designs.

Matched-Pairs Design

It is assumed that subjects are matched into pairs a priori of treatment assignment using covariate information

or other subjective information thought to create homogeneity of treatment outcomes within pairs. Subjects are arbitrarily labeled within pairs as Subject 1 and Subject 2. Two treatments, T or C , are assigned within pairs via a random coin toss. There are $N = 2n$ subjects in a study resulting in n matched pairs. The potential outcomes are, again, defined using variables (X, Y) for outcomes to T and C , respectively.

Continuous Outcomes

One way to parameterize the set of $2n$ potential outcomes was shown by Gadbury.^[35] This is shown below along with one pattern of observed outcomes post treatment assignment.

$$\left(\begin{array}{cc} X_1 - \varepsilon_1 & Y_1 - \eta_1 \\ X_1 + \varepsilon_1 & Y_1 + \eta_1 \\ \text{-----} & \text{-----} \\ X_2 - \varepsilon_2 & Y_2 - \eta_2 \\ X_2 + \varepsilon_2 & Y_2 + \eta_2 \\ \text{-----} & \text{-----} \\ \vdots & \vdots \\ \text{-----} & \text{-----} \\ X_n - \varepsilon_n & Y_n - \eta_n \\ X_n + \varepsilon_n & Y_n - \eta_n \end{array} \right) \xrightarrow{\text{Treatment Assignment}} \left(\begin{array}{cc} X_1 - \varepsilon_1 & ? \\ ? & Y_2 + \eta_1 \\ \text{-----} & \text{-----} \\ ? & Y_2 - \eta_2 \\ X_2 + \varepsilon_2 & ? \\ \text{-----} & \text{-----} \\ \vdots & \vdots \\ \text{-----} & \text{-----} \\ ? & Y_n - \eta_n \\ X_n + \varepsilon_n & ? \end{array} \right) \quad (6)$$

A true individual treatment effect for Subject 1 in the i th pair is $D_{i1} = X_i - Y_i - (\varepsilon_i - \eta_i)$ and for Subject 2 it is $D_{i2} = X_i - Y_i + (\varepsilon_i - \eta_i)$. The average treatment effect for the two subjects in the i th pair is $X_i - Y_i$, and the two individual effects are not equal unless $\varepsilon_i = \eta_i$. The parameters, ε_i, η_i , $i = 1, \dots, n$, reflect the quality of the matching criteria. An observed treatment effect for the i th pair can be written as,

$$d_i = \{X_i - Y_i - (\varepsilon_i + \eta_i)\}\delta_i + \{X_i - Y_i + (\varepsilon_i + \eta_i)\}(1 - \delta_i) \quad (7)$$

where $\delta_i = 1$ implies that Subject 1 received treatment T and Subject 2 received treatment C ; if $\delta_i = 0$, the assignment is reversed for that pair and $P(\delta_i = 1) = 1/2$ for each pair. The condition, $\varepsilon_i = \eta_i = 0$, $i = 1, \dots, n$, is sufficient for equating an observed treatment effect for a pair with the true effects for the two individuals in the pair. S-T interaction can then be directly estimated using the variance of the observed paired differences.

Binary Outcomes

Gadbury, Iyer, and Albert^[29] presented the issues involved in estimating π_2 in the population model shown in expression 3 using a matched-pairs design. There are now 16

outcomes in the potential outcomes framework, with four possible outcomes for each subject in a pair. The potential outcomes for Subjects 1 and 2 in a pair are represented by $\{(X_1, Y_1), (X_2, Y_2)\}$. Four (of the 16) outcomes reflect subjects who are perfectly matched on both variables. These outcomes are $\{(x_1, y_1), (x_2, y_2)\} = \{(0,0), (0,0)\}, \{(0,1), (0,1)\}, \{(1,0), (1,0)\},$ and $\{(1,1), (1,1)\}$. If the sum of the probabilities for these four outcomes is equal to 1, then only perfectly matched pairs are available in the matched population.

Suppose subjects have been randomly labeled within each of n pairs and, without loss of generality, Subject 1 in each pair receives treatment T and Subject 2 receives treatment C . So observable variables for a pair are of

the form (X_1, Y_2) and resulting data are of the form for the usual matched 2×2 table for binary outcomes, or can be shown as

X_1	Y_2	Frequency
0	0	s_1
0	1	s_2
1	0	s_3
1	1	s_4

(8)

where $\sum_i s_i = n$. Gadbury, Iyer, and Albert 19 showed that a sufficient condition for s_i/n to be unbiased for π_i is that the population of matched subjects are matched on at least one of the two potential outcome variables; that is, the proportion that are mismatched on both X and Y equals zero. There are four potential outcomes that are a double mismatch, but exchangeability within pairs (as a result of the random labeling) allows for these four to be expressed as two unique double mismatches: $\{(x_1, y_1), (x_2, y_2)\} = \{(0,0), (1,1)\}$ and $\{(x_1, y_1), (x_2, y_2)\} = \{(0,1), (1,0)\}$. A necessary and sufficient condition for s_i/n to be unbiased for π_i is that the probabilities of these two different occurrences of a double-mismatched pair are equal.^[29]

Of course, without additional information, one will not know how well subjects are matched in the population. One can still obtain bounds for π_i similar to what was shown earlier for the two independent sample framework. The quality of the matching criteria cannot be evaluated using observed data unless the design is altered to facilitate this. For example, some pairs could be selected so that both subjects in the pair received treatment T , and other pairs where both subjects received treatment C . Gadbury, Iyer, and Albert^[29] constructed a simulated example where $\pi_2 = 0.125$, and an estimated upper bound for π_2 without this design extension was 0.34. After using the extension to the design that provided information on the matching criteria, the estimated upper bound was tightened to 0.21.

An obvious extension to these results for matched pairs is to using covariates or other information on subjects to group subjects into homogeneous blocks. This design will likely be of more practical use to researchers. Evaluating S-T interaction in this type of design for a binary outcome variable was developed and reported in Albert et al.^[37]

A Two-Period Crossover Design

When feasible to implement, the crossover design allows a direct observation for an individual effect as outcomes for each subject are observed for both treatments. (For more discussion on this, see Ref. [15] and for more details on crossover designs in general, see Ref. [38], or [39] for a review of papers on crossover designs.) As mentioned earlier, these designs have been used in individual bioequivalence studies. Whether or not these observed individual effects are true individual effects depends on how one defines a true individual effect. Suppose that $N = 2n$ subjects are in a trial and that during the first time period, n will be randomly selected to receive treatment T with the other n receiving C (this balance in the design is not necessary but is simply used for convenience). At some point in time (time 1), outcomes are observed. After a washout period, treatment assignments are reversed and at some second point in time (Time 2), outcomes are observed. The two sequences can be abbreviated TC (i.e., treatment T in period one and control C in period 2) and CT (control C in period 1 and treatment T in period 2). It is assumed that the washout period is sufficient so that there are no carryover effects of treatments at Time 1 to Time 2. Potential outcomes for this scenario were shown by Gadbury^[35] and are repeated below.

Subject	Time 1		Time 2	
1	$X_1 - t_1$	$Y_1 - \tau_1$	$X_1 + t_1$	$Y_1 + \tau_1$
$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$
$2n$	$X_{2n} - t_{2n}$	$Y_{2n} - \tau_{2n}$	$X_{2n} + t_{2n}$	$Y_{2n} + \tau_{2n}$

(9)

There is a true individual treatment effect for each subject at each time period. The parameters t, τ reflect time effects from Time 1 to Time 2. It may be reasonable to define a true

individual treatment effect for the i th subject as a combination of the two effects at each time period. The average will be used here so the true treatment effect for the i th subject is $D_i = (1/2)\{(X_i - t_1) - (Y_i - \tau_1) + (X_i + t_2) - (Y_i + \tau_2)\} = X_i - Y_i$. Let $\delta_i = 1$ if the i th subject is assigned the first treatment sequence, T then C , and $\delta_i = 0$ if assigned the reverse sequence, C then T . The observed treatment effect for the i th subject is $d_i = \{(X_i - t_1) - (Y_i + \tau_2)\}\delta_i + \{(X_i + t_2) - (Y_i - \tau_1)\}(1 - \delta_i)$. A sufficient condition for this observed effect to equal the true effect is that $(t_1 + \tau_2) = 0$, meaning that the sequence to which the subject was assigned had no effect on outcomes. Bounds for the variance of individual treatment effects, σ_D^2 , will depend on nonestimable parameters in the distribution of time effects, particularly the variance-covariance matrix of (t, τ) . If a Balaam design is used, where some subjects are allocated to receive the same treatment in both time periods (i.e., include the sequences TT and CC in the above design), then variances of the time effect parameters can be estimated but the correlation cannot.^[40] Still, bounds for σ_D^2 should be estimable by letting the correlation range from -1 to 1 .

CONCLUSION

This entry highlighted the role of potential outcomes for defining individual treatment effects and quantifying S-T interaction. Three designs were discussed and a few details were provided for the two-sample completely randomized design. Evaluating the degree of S-T interaction, and its consequences, is a challenging problem and often only bounds can be derived that can be directly estimated using data. The ability to estimate S-T interaction requires assumptions about the degree to which “observed individual treatment effects” are equal to true individual effects. These assumptions may be perfectly reasonable in many applications where much is known about the treatment and/or the disease that is being treated. Such clinical knowledge and past experience are often outside the realm of what data can show in a single experiment. This entry demonstrated some limitations of using data alone to evaluate individual treatment heterogeneity. It is hoped that this will help illuminate the assumptions that are made when equating observed heterogeneity with true heterogeneity and, thus, help investigators to evaluate the reasonableness of such assumptions in particular contexts. Perhaps new designs or extensions to current designs will be considered for clinical trials with an added goal in mind, as Longford remarked, “... inference about the mean treatment effect be supplemented by inference about the variation of the treatment effects”. (p. 1473)^[7]

Abstract

Surrogate endpoints play a particularly important role in the early development of a pharmaceutical product. This entry reviews the benefits and the limitations of using surrogate endpoints and provides statistical analysis and regulatory requirements.

INTRODUCTION

In the development of a pharmaceutical product, a crucial step is to conduct clinical trials demonstrating the efficacy and safety of this product. The measurement used to evaluate the effect of the treatment is termed an *endpoint*. Endpoints used to measure clinical benefit, such as prolongation of survival time and reduction of mortality rate, are usually considered “true” endpoints because clinical benefit is the ultimate purpose of a medical treatment. However, the feasibility and practicality of measuring a “true” endpoint may be limited because of various reasons. Therefore it is crucial to have some alternative measurement that would allow early assessment of a potential treatment effect.

OVERVIEW

The most important reason that limits the use of a “true” endpoint is the time and the cost needed to conduct clinical trials. For example, time to death from the time of enrollment in a clinical trial is frequently used as an endpoint to evaluate a treatment for a life-threatening disease such as cancer or AIDS. However, to use survival time as the endpoint may require several hundred patients and several years of follow-up. During the process of developing a new drug, without evidence that the new product may be effective, it is unlikely that a sponsor will be willing to devote a large resource to a clinical trial that will take years to demonstrate a candidate’s therapeutic viability. The need to reduce the duration of clinical trials becomes more urgent in the search for treatment for life-threatening diseases.

Other factors may also limit the use of a “true” endpoint. For example, a new treatment may be developed during the trial period, making the treatment under investigation obsolete. Additionally, competing risk, i.e., death as a result of other reasons during the trial, constitutes another

problem for the evaluation of the treatment effect of the drug. These problems become more serious with longer follow-up times. Finally, the use of a “true” endpoint may also be limited by the current knowledge and technology for measuring the endpoint. One example is pain, which cannot be measured directly and objectively because of the current limited knowledge about pain. Because in most cases objective measurements, which are proven to be sensitive to the “true” degree of pain, are either difficult to obtain or do not exist, most clinical trials rely on patient self-assessment of pain as the endpoint, which can be viewed as the “surrogate” for the “true” severity of pain.^[1]

The limitations of “true” endpoints prompted the use of *surrogate endpoints*. A surrogate endpoint “is an endpoint that is intended to relate to a clinically important outcome but does not in itself measure a clinical benefit.”^[2]

A surrogate endpoint is sometimes referred to as an *intermediate endpoint*^[3,4] or a *surrogate marker*.^[5–7] A *marker* usually refers to some laboratory test result that is associated with a certain disease, usually indicating the progress of the disease. For example, significant elevations of SGOT and SGPT are strong indications for hepatitis or other liver damage, so they are considered markers for hepatitis. Similarly, an increase in HIV viral load usually indicates a worsened condition for AIDS patients, so HIV viral load is a marker for the progression of AIDS. A marker can be used to detect diseases, monitor disease progression, or predict clinical outcome, and because of its strong association with the clinical endpoint, it can also be used as a surrogate for the “true” endpoint. The focus of this discussion will be on the use of a surrogate marker as an endpoint, and the terms surrogate endpoint and surrogate marker may be used interchangeably. Because of the fact that a change in a surrogate endpoint occurs prior to a change in a “true” endpoint—for instance, an increase in HIV viral load occurs before the onset of AIDS—a surrogate endpoint may also be referred to as an intermediate endpoint.

Table 1 Typical Cardiovascular Trials with Surrogate and True Endpoints: Sample Sizes and Follow-Up Periods

Event	True endpoint trial			Surrogate endpoint trial		
	Endpoint	Size	Length	Endpoint	Size	Length
Myocardial infarction	Death	4,000	5 yr	Coronary artery patency	200	90 min
Myocardial infarction	Death	4,000	5 yr	Ejection fraction	30	2–4 wk
Stroke	Stroke	25,000	5 yr	Diastolic blood pressure	200	1–2 yr

Copyright © John Wiley & Sons Limited. (From Ref. [8].)

The use of surrogate endpoints can significantly reduce the follow-up time and sample size required to demonstrate treatment effect in a clinical trial. As an example, [Table 1](#)^[8] illustrates the reduction in time and cost resulting from using surrogate endpoints in clinical trials for the treatment of cardiovascular diseases.

Surrogate endpoints play a particularly important role in the early development of a pharmaceutical product, when surrogate endpoints can be used to demonstrate if the drug has any pharmacological effect, as postulated by the *in vitro* model or in preclinical *in vivo* results. Additionally, surrogate endpoints can provide guidance in selecting a dose range for later confirmatory trials.

It has been suggested that the “true” endpoint usually measures clinical benefit, and the surrogate endpoint measures mostly a specific aspect of disease progression.^[8] For a given disease, there can be different stages and different biological mechanisms affecting the progress of the disease. As a result, for a specific disease, the surrogate endpoint may change depending upon the stage of the disease as well as the specific physiopathological mechanism that the drug is targeting. For instance, both serum cholesterol level and diastolic blood pressure are widely used surrogate endpoints for coronary heart disease. To decide which of these two is appropriate to use will depend on the biological action of the drug under study. [Table 2](#)^[9] presents surrogate endpoints used in developing an antidiabetes drug. It can be seen that the choice of a surrogate endpoint depends upon the stage of diabetes as well as on the stage of the drug development, *i.e.*, whether it is an early- or late-phase clinical trial. [Table 2](#) shows that the sample size and the treatment duration also change according to the stage of drug development. Early-phase trials tend to be shorter and use fewer people as compared with the late-phase trials.

A potential surrogate is identified in several ways.^[8] The core for identifying a surrogate endpoint is a strong biological rationale. For example, any effective treatment for cancer must have some effect on the tumor itself, which suggests that tumor shrinkage might be used as a surrogate endpoint in the studies of cancer treatment. Epidemiological studies can also reveal endpoints that have strong predictive values to the clinical outcome. For instance, in many observational studies for AIDS, CD4 lymphocyte counts were shown to be the most powerful predictor of disease progression and

subsequent survival.^[10–13] This led to the extensive use of CD4 counts as a surrogate endpoint in early AIDS research. Lastly, clinical trials may also indicate a potential surrogate endpoint. In a clinical trial, if a treatment that suppresses a given marker produces more clinical benefit than another treatment that does not suppress the marker, that marker may be used as a potential surrogate endpoint. However, the use of the surrogate endpoints identified through these ways needs to be validated through further studies.

SCIENTIFIC ISSUES—LIMITATIONS OF USING SURROGATE ENDPOINT

Although yielding potentially important benefits, the use of surrogate endpoints can sometimes introduce ambiguous results and thus generate controversy:

There are two principal concerns with the introduction of any proposed surrogate variable. First, it may not be a true predictor of the clinical outcome of interest. For example, it may measure treatment activity associated with one specific pharmacological mechanism, but may not provide full information on the range of actions and ultimate effects of the treatment, whether positive or negative. There have been many instances where treatments showing a highly positive effect on a proposed surrogate have ultimately been shown to be detrimental to the subjects' clinical outcome; conversely, there are cases of treatments conferring clinical benefit without measurable impact on proposed surrogates.^[14]

Some cancer treatments provide an example of a treatment that has a positive effect on the surrogate endpoint but a detrimental effect on a patient's health. In this instance, although a treatment may achieve a certain degree of tumor shrinkage, the toxicity of the drug itself may in fact worsen a patient's general health and thus shorten survival time. Conversely, in AIDS trials, it has been shown that many treatments with a positive effect on survival time have null or even a negative effect on CD4 count, the proposed surrogate.^[15] A second concern relating to the use of surrogate endpoints is that “the proposed surrogate variables may not yield a quantitative measure of clinical benefit that can be weighed directly against adverse effects.”^[14]

Table 2 Clinical Endpoints vs. Surrogate Endpoints in Different Phases of Clinical Trials for Diabetes

Clinical endpoint	Phase	Subject characteristics	Group sample size	Treatment duration	Surrogate endpoints
Acute glucose lowering	I	Normals or diabetics	6–12	≥ Single dose	◆ Plasma glucose ◆ Plasma insulin ◆ Other (e.g., insulin clamp)
Improved glycemic control	I	Diabetics	12–36	2–12 wk	◆ Plasma glucose ⇒fasting ⇒2-hr postprandial ⇒24-hr profile
	III	Diabetics	40–200	6–12 mo	◆ Glycohemoglobin (HBA _{1c}) ◆ Glycated serum proteins ◆ Hypoglycemic episodes
Complications: anatomic/physiologic benefit	II–III	Diabetics with early complications	50–300	6 mo–2 yr	◆ Nerve conduction velocity ◆ Nerve/kidney biopsy ◆ Albuminuria, a GFR ◆ Funduscopy
Complications: actual clinical benefit	IV	Diabetics with early or no complications	200–800	≥ 3–5 yr	◆ Neuropathic pain ◆ Sensorimotor deficit ◆ GFR, renal failure ◆ Visual acuity ◆ Direct and indirect costs

(From Ref. [9].)

REGULATORY REQUIREMENTS

As just mentioned, the use of surrogate endpoints has limitations. However, in the case of life-threatening diseases, where the availability of a new treatment may save many lives, there is a strong need to reduce the duration of a clinical trial and to accelerate drug approval, and, very often, using a surrogate endpoint is necessary to evaluate a treatment more quickly.

The Food and Drug Administration (FDA) issued guidelines for accelerated approval based on the surrogate endpoints. The guideline states that:

FDA may grant marketing approval on the basis of adequate and well-controlled clinical trials establishing that the drug product has an effect on a surrogate endpoint that is reasonably likely, based on epidemiologic, therapeutic, pathophysiologic, or other evidence to predict clinical benefit or on the basis of an effect on a clinical endpoint other than survival or irreversible morbidity. Approval under this section will be subject to the requirement that the applicant study the drug further, to verify and describe its clinical benefit, where there is uncertainty as to the relation of the surrogate endpoint to clinical benefit or of the observed clinical benefit to ultimate outcome.^[15]

STATISTICAL METHODS

In the effort to identify reliable surrogate endpoints, several statistical methods have been proposed. In 1987, Prentice^[16] introduced the following statistical definition of a surrogate endpoint as “a response variable for which a test

of the null hypothesis of no relationship to the treatment groups under comparison is also a valid test of the corresponding null hypotheses based on the true endpoint.” Based on this definition, he proposed the use of the following two conditions as the operational criteria to determine a surrogate:

$$\lambda_T\{t; S(t), x\} = \lambda_T\{t; S(t)\}$$
 (1)

and

$$\lambda_T\{t; S(t)\} \neq \lambda_T(t)$$
 (2)

where t denotes the time from enrollment in a clinical trial, T denotes a true time-to-failure endpoint, $x = (x_1, \dots, x_p)$ consists of indicator variates for $p \geq 1$ of the $p + 1$ treatments to be compared in respect to the corresponding (instantaneous) failure rate, $\lambda_T\{t; x\}$, and $S(t) = \{Z(u); 0 \leq u < t\}$ denotes the history prior to time t of a possibly vector-valued stochastic process $Z(U) = \{Z_1(u), Z_2(u), \dots\}$, which may be used to specify a surrogate for T .

Criterion 1 requires that conditioning on the surrogate marker process, the treatment is independent of the failure rate for T . Thus the surrogate marker captures all the treatment effect of x on T . Criterion 2 requires that the surrogate marker has some predictive value to T . Recall that in “Introduction,” it was noted that a surrogate endpoint must have strong predictive value to the clinical outcome. The Prentice criterion of Eq. 2 is equivalent to this requirement. Between the two criteria, Eq. 1 is considered the principal criterion.^[17]

Although expressed in terms of survival analysis, these criteria can be interpreted in a general way. Feigal,^[18] from the FDA, expressed the following heuristic model for a drug effect:

$$\text{Outcome} = \text{Placebo rate} + \text{Drug effect}$$

In the instance of a surrogate marker, he further decomposed the model as

$$\begin{aligned} \text{Outcome} = & \text{Placebo rate} + \text{SM drug effects} \\ & + \text{Other drug effects} \end{aligned}$$

where SM is the abbreviation of surrogate marker. He pointed out that the Prentice criterion of Eq. (1) requires essentially that conditioning on the surrogate marker, the “other drug effects” reduce to 0.

This Prentice criterion is very strict. In 1992, Freedman and Graubard^[3] proposed another criterion for validating a surrogate, which is less stringent than that of Prentice. The development of Freedman and Graubard’s criterion is described briefly next.

With a slight change in notation, let T be a binary outcome, X indicate the treatment groups, and S denote the surrogate endpoint. Then the Prentice criteria can be rewritten as

$$P(T = 1 | S, X) = P(T = 1 | S) \quad (3)$$

and

$$P(T = 1 | S) \neq P(T = 1) \quad (4)$$

For simplicity, assume that there are two treatment groups ($X = 1$ and $X = 2$) and that S is discrete and takes k values $s_1, \dots, s_k$. Let $p(T = 1 | S = s_i, X = j) = p_{ij}$, then Eq. (3) is equivalent to

$$p_{i1} = p_{i2} \quad (i = 1, \dots, k) \quad (5)$$

Consider the following model:

$$g(p(T = 1 | S, X = j)) = h(S) + \tau_j \quad (6)$$

where S and X have an additive effect on some function (g) of the probability of disease, $h(S)$ is some function of S , and τ_j is the j th treatment effect. If we further choose logit function for g and assume that

$$h(S) = \mu + \sigma_i$$

where μ represents the overall mean, then Eq. (6) becomes the usual linear logistic model with the constraint of $\sigma_1 + \dots + \sigma_k = 0$ and $\tau_1 + \tau_2 = 0$, and it can be further expanded to include other effects. Consequently, the test of the null hypothesis (Eq. [5]) becomes the test of $\tau_1 = \tau_2 = 0$.

If this hypothesis is rejected, S cannot be used as a surrogate endpoint. However, the lack of significance in this test does not warrant S to be a valid surrogate endpoint. To quantify further the effect of S , consider the quantity

$$1 - \frac{\hat{\tau}_{1a}}{\hat{\tau}_1}$$

where $\hat{\tau}_{1a}$ is the adjusted (by S) treatment effect in group 1 and $\hat{\tau}_1$ is the unadjusted treatment effect in group 1. This quantity is the estimate of the proportion of the drug effect that is explained by the surrogate endpoint. Under the criteria of Prentice, this proportion is expected to equal 1. However, we may allow this proportion to be larger than some critical values, such as 0.5 and 0.75, but less than 1. In other words, we may allow the surrogate endpoint to explain a large portion of the drug effect but not all of the effect. Using the notation in the heuristic model, Feigal^[18] presented Freedman and Graubard’s^[3] model as

$$\begin{aligned} & \text{Proportion of drug effect attributed to SM drug effects} \\ &= \frac{\text{SM drug effects}}{\text{Total drug effects}} \end{aligned}$$

RECENT DEVELOPMENTS

The use of surrogate endpoints in clinical trials is an important issue because they can significantly reduce the duration and the cost of clinical trials and thereby accelerate the development of medical treatments. Surrogate endpoints had long been used to assess treatment effects, especially for rare and life-threatening diseases. However, there is some controversy surrounding their use. In 1987, a meeting was held to discuss these issues.^[1,8,16,19,20] In this meeting, Prentice proposed statistical operational criteria to identify surrogate endpoints.^[16] Since then, Prentice’s criteria, as described earlier, have been applied by several researchers and have been used to evaluate several commonly used surrogate markers.^[17,21] In 1992, the FDA issued regulations for accelerated approval based on the surrogate endpoints for new drugs and biological products treating serious or life-threatening illness.^[22] In the same year, Freedman and Graubard^[3] proposed the modification to Prentice’s criteria, making the criteria less stringent. These criteria have also been applied to biomedical research.^[6] In addition, other methods, such as using meta-analysis to identify surrogate endpoints, have also been proposed.^[23]

In recent years, the FDA has issued several guidelines prepared under the auspices of the International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use.^[2,14,15] The use of surrogate endpoints was discussed in the “general considerations for clinical trials”^[2] and was specifically

addressed in “guideline on statistical principles for clinical trials.”^[14] The FDA later established a “surrogate marker methodology group” to evaluate each potential surrogate endpoint.^[18] The FDA’s guideline for each disease also includes the use of a specific marker as a surrogate endpoint for that disease.

In addition to the use of a surrogate endpoint in place of the true endpoint for the efficacy analysis, different methods have been proposed in which a surrogate endpoint was used to improve the efficiency of the estimate of the treatment effect on the true endpoint. Flandre and O’Quigley^[24] proposed a two-stage approach. In the first stage, the relationship between the true and the surrogate endpoints, both measured for all subjects, is examined. This relationship is then applied in the second stage to other subjects, where the follow-up will be terminated once the surrogate endpoint is observed. Lefkopoulou and Zelen^[4] proposed a test to examine the impact of an intermediate endpoint on the true endpoint, which is the survival time. Cox^[25] proposed a method using a surrogate endpoint to recover information and predict the survival distribution in the case of right censoring. This idea was further extended by Fleming et al.,^[17] and they referred to the endpoint that provides additional information on the true endpoint as an *auxiliary endpoint* (referred to as a surrogate endpoint in the paper by Cox^[25]) and distinguished it from the surrogate endpoint. Kosorok and Fleming^[26] also proposed a method using surrogate failure-time data to increase efficiency in estimating the treatment effect on the true endpoint.

CONCLUSION

As medical science advances, human beings are revealing the mystery of many complicated diseases, which may take decades to evolve, such as Alzheimer’s disease. In the process of studying these diseases, the use of surrogate endpoints is almost inevitable. With the help of the development of medical technologies, such as the study of genes and protein structure, as well as the development of statistical methods, more reliable surrogate endpoints will be identified to enable humankind to understand an increasing number of diseases. Meanwhile, one should keep in mind the limitation of the surrogate endpoints, and use them with caution.

Survival Analysis

Dirk F. Moore

Department of Biostatistics, University of Medicine and Dentistry of New Jersey School of Public Health, New Jersey, U.S.A.

Abstract

Survival analysis is the study of time-to-event data. The distinguishing characteristics of such data are well-defined starting and ending points. This entry reviews a randomized clinical trial example and several models for comparing survival analyses.

INTRODUCTION

Survival analysis is the study of time-to-event data. The distinguishing characteristics of such data are well-defined starting and ending points, and examples may be found in such diverse fields as demography, actuarial science, engineering, medicine, and epidemiology. Survival data are often subject to *right censoring*, a form of incomplete observation in which some endpoints are only known to be greater than an observed censoring time. In a clinical trial, for example, right-censored observations can occur when subjects drop out of a study, or if a study ends before all subjects have experienced the endpoint of interest. Other forms of incomplete observation include left and interval censoring, and a form of length-biased sampling known as truncation. Correctly accounting for censoring and truncation is essential for obtaining unbiased estimates of the survival distribution and for drawing correct inferences.

A RANDOMIZED CLINICAL TRIAL EXAMPLE

A randomized clinical trial of survival is an experimental method for comparing the survival time distributions of two (or possibly more) treatments for a disease. The survival time is the time from when a patient enters the trial until and the occurrence of an event of interest. This event could be death or recurrence of disease, or even a positive event, such as response to treatment; the key requirement is that the event-of-interest be precisely defined. In the first phase of a trial, called the accrual period, patients are entered into a trial and randomly assigned to one of the treatments. After a desired number of patients are entered, accrual is closed, and the patients who have been entered are followed for a specified period of time known as the follow-up period. A feature of most clinical trials is that at the end of the follow-up period, some patients may not yet have experienced the event of interest. These patients are said to be right-censored—their time-to-event has not

been observed, but is known to exceed the censoring time. For each patient two variables are recorded. The first, the time from entry until the event of interest or, for censored patients, the time from entry until the end of follow-up, is known as the *survival time*. The second variable is a *censoring indicator*, a binary observation that indicates whether the observed survival time is the time to an event or the time to censoring. The goal of the study is to compare the survival times of patients receiving each of the treatments, while correctly accounting for the censoring. A key assumption is that the censoring must be independent of the survival times. This assumption must be carefully assessed, particularly if there is censoring due to patient drop-out.

A simple example, which is typical of randomized clinical trials, is a study comparing the efficacy of maintenance therapy for patients with acute myelogenous leukemia, or AML.^[1] A total of 23 patients in remission following chemotherapy were randomly assigned to either receive or not receive maintenance therapy, and the survival times were defined to be time from randomization until recurrence of disease or censoring. The survival times (remission times in weeks) are as follows:

Maintained group: 91313+182328+313445+48161+

Non – maintained group: 55881216+232730334345

For example, the first two patients in the maintained group were in remission for 9 and 13 weeks, respectively, before recurrence of disease. The third patient in the maintained group was censored at 13 weeks; that is, that patient was still in remission at the end of the follow-up period. The other observations are interpreted in an analogous manner. These results may be presented as *Kaplan-Meier survival curves* (Fig. 1). These survival curves are plots of the estimated probability of being disease-free versus the number of weeks from randomization. Note that both curves start at 1 (the probability of being disease-free at the time of randomization) and decrease as a step function over time,

Fig. 1 Kaplan-Meier survival curves for the AML maintenance study

with steps occurring at the event times. Censoring times are indicated by short vertical marks. Visual inspection of the two survival curves shows that, in this trial, patients receiving maintenance therapy remained disease-free longer on average than did patients not receiving the therapy. However, drawing an inference about the difference between two treatments requires a *log rank test*, a specialized procedure for comparing censored survival data discussed later in this article.

SURVIVAL FUNCTIONS AND HAZARD RATES

Let $T > 0$ denote a survival random variable. The survival function is defined to be $S(t) = \text{pr}(T > t)$, and gives, for any time t , the probability that the random variable T exceeds t . Thus, $S(0) = 1$, and the function S is a decreasing (or, more precisely, a monotone non-increasing) function of t . A closely related function is the cumulative distribution function, or (in epidemiology) the cumulative risk of disease, defined by $F(t) = 1 - S(t)$. The probability density function is defined by $f(t) = -\frac{dS(t)}{dt}$. For survival data it is often more convenient to work with the *hazard* function, which may be thought of as the instantaneous risk of failure. Formally, this may be written as

$$h(t) = \lim_{\Delta \rightarrow 0^+} \frac{\text{pr}(t \leq T < t + \Delta \mid t \leq T)}{\Delta},$$

that is, the probability that a subject who has survived up to time t will fail in the next “instant” of time, Δ . In terms of the survival and density functions, this may be written as $h(t) = f(t)/S(t)$. Another useful result is that the survival function may be written in terms of the hazard function as follows:

$$S(t) = \exp \left\{ - \int_0^t h(u) du \right\}.$$

Using these formulas, one may derive the survival function from the hazard function, and vice versa.

PARAMETRIC SURVIVAL MODELS

One approach to modeling survival data is to construct a likelihood function using a parametric family of survival distributions. One may then use standard likelihood theory for estimation and testing. The simplest parametric family for survival analysis is the *exponential* distribution. Its survival and hazard functions are given by $S(t) = e^{-\lambda t}$ and $h(t) = \lambda$, respectively, where λ is called a *rate* parameter. Note that the hazard function is constant over time, indicating that the risk of failure is the same regardless of how long a subject has survived. This is often known as the lack-of-memory property, and limits its usefulness in many applications; human survival times in particular rarely have this property.

The *Weibull* distribution is a more flexible distribution. Its survival and hazard functions are given by $S(t) = \exp(-\lambda t^\alpha)$ and $h(t) = \alpha \lambda t^{\alpha-1}$, respectively, where λ is a scale parameter and α is a *shape* parameter. Three examples of Weibull hazard functions for various choices of the shape parameter are given in Fig. 2. Note that the exponential distribution results as a special case when $\alpha = 1$.

Other distributions useful in survival analysis include the *gamma* and *log-normal* distributions. Details of these and other parametric distributions may be found in, for example, Klein and Moeschberger^[2] and Cox and Oakes.^[3]

Once a parametric model is chosen, it may be fitted to a survival data set by constructing a *likelihood* function. This likelihood consists of a product of factors (if the observations are independent), one for each subject. For data that include right-censored observations, and assuming that the censoring is independent of the failure times, the likelihood may be written as follows:

$$L(\theta) = \prod_{i \in D} f(t_i; \theta) \prod_{i \in C} S(t_i; \theta),$$

where D denotes the set of all subjects who are observed to fail, C denotes the set of subjects who are right-censored, and θ denotes the parameters that define the parametric model. As before, f and S denote the probability density function and survival function, respectively. If the data set

Fig. 2 Weibull hazard functions with $\lambda = 1$ various choices of α . Note that the case when $\alpha = 1$ corresponds to an exponential hazard function

includes subjects who are subject to left or interval censoring, or truncation (due to length-biased sampling), they may be entered into the likelihood using appropriate factors.^[2] Once a likelihood function has been defined, the parameters θ may be estimated using maximum likelihood techniques.

If a parametric family with a sufficiently flexible hazard can be found, estimation and testing may be carried out using standard likelihood theory. The strength of parametric modeling lies in its relative simplicity; complex sampling experiments, as well as clustered survival times, may often be accommodated in a relatively straightforward way. However, a parametric model may not accurately represent the true distribution of survival times, and thus may lead to biased estimates of parameters and incorrect inferences. Additional flexibility in modeling the hazard function may be obtained by using the *piecewise exponential* distribution. In this generalization of the exponential, the hazard function is constant within a small number of specified intervals, but is free to vary from one time interval to the next.^[2] This model may be used in applications where simple parametric models do not provide the needed modeling flexibility, and where fully non-parametric models are not computationally tractable. An example of this may be found in Moore et al.,^[4] who develop a non-standard likelihood for estimating the age-of-onset distribution of breast cancer among carriers of a genetic mutation.

NON-PARAMETRIC SURVIVAL MODELS

Unlike parametric methods, non-parametric survival methods make minimal assumptions about the shape of the hazard function. These methods are derived from actuarial life-table methods, in which time is divided into a number of intervals (often five-year intervals), and the probability of surviving each interval is computed. The survival distribution is computed as a cumulative product of these probabilities. The product-limit estimator, also known as the Kaplan-Meier estimator, of the survival distribution results when the time intervals are sufficiently small that only one event occurs per interval,^[5] although modifications for tied observation times are possible, as discussed by numerous researchers (e.g., Ref. [3]). An asymptotically equivalent method, known as the Nelson-Aalen estimator, models the hazard as a piecewise constant exponential distribution, again with one event per interval.^[2] The flexibility of these models has made them among the most frequently used for modeling human survival data. The Kaplan-Meier and Nelson-Aalen estimators of the survival function are given by, respectively,

$$\hat{S}_{KM}(t) = \prod_{t_i \leq t} \left(1 - \frac{d_i}{r_i}\right)$$

$$\hat{S}_{NA}(t) = \exp \left\{ - \sum_{t_i \leq t} \frac{d_i}{r_i} \right\}$$

where the t_i are the failure times, r_i is the number of subjects at risk at time t_i , and d_i is the number of failures that occur at time t_i . Both of these estimates yield step-function estimates, as in the example shown in Fig. 1.

COMPARING SURVIVAL CURVES

One may compare two survival curves by computing a *log rank statistic*,

$$U = \sum_{t_i \in D} \left(d_{1i} - \frac{d_i r_{1i}}{r_i} \right)$$

It has variance

$$V = \sum_{t_i \in D} d_i \frac{r_{0i} r_{1i} (r_i - d_i)}{r_i^2 (r_i - 1)},$$

where D is the set of all failure times, d_{1i} and d_i are the numbers of deaths at time t_i in group 1 and in both groups 0 and 1, respectively, r_{0i} and r_{1i} are the numbers of subjects at risk for failure at time t_i in groups 0 and 1, respectively, and $r_i = r_{0i} + r_{1i}$. The *log rank test* for a difference of two survival curves is based on the statistic $Z = U/V^{1/2}$, which has approximately a standard normal distribution. A weighted version of U , with weights given by $w_i = n\hat{S}(t_i)$, is known as the Prentice modification of the Gehan statistic. This modified statistic places more weight on early survival differences; details may be found in Cox and Oakes.^[3]

Sample size calculations for a two-sample log-rank test with a specified significance level α and power may be conducted most directly in terms of the number of events d required to detect a log-hazard ratio $\beta = \log[\lambda_1(t)/\lambda_0(t)]$ between two groups with hazard functions $\lambda_1(t)$ and $\lambda_0(t)$, respectively. For equal numbers in the two groups, the total number of events required is given by

$$d = \frac{4(z_\alpha + z_{1-\text{power}})^2}{\beta^2}.$$

Selection of an appropriate value of β may be made in terms of the inverse of the desired ratio of median survival times. For example, if the survival times are exponentially distributed, the required β is given by $\beta = \log_e(m_0/m_1)$, where m_1 and m_0 are the median survival times in groups 1 and 0, respectively. See Therneau and Grambsch^[6] for additional approaches to selecting β for estimating a sample size.

A more difficult problem is to calculate the total number of subjects that must be enrolled into a trial to produce d events. The total number depends on the lengths of the accrual and follow-up periods and on the survival functions in the control and treatment groups. Of course, the larger the amount of censoring that a design calls for, the larger

the total sample size will need to be to produce the required number of events. See Schoenfeld^[7] for details.

A covariate vector $\tilde{z}$ may be accommodated using the *proportional hazards model*,^[8] in which an individual's hazard function is given by

$$\lambda(t; \tilde{z}) = \lambda_0(t) \exp(\tilde{z}\beta).$$

Here $\lambda_0(t)$ is a nonparametric baseline hazard function, and $\exp(\tilde{z}\beta)$ is a multiplicative constant. Estimation of the covariate vector β proceeds via a *partial* likelihood, a semi-parametric version of a likelihood. The *log rank test* discussed earlier may be derived from the proportional hazards model by using a treatment indicator variable as the covariate z and constructing a *score test* of $H_0: \beta = 0$.^[3] The mathematical underpinnings of the non-parametric survival curve methods and the semi-parametric Cox model are based on the theory of counting processes and martingale theory.^[9,10]

Covariate information may also be accommodated using parametric models.^[3] Parametric models lack the flexibility of the Cox proportional hazards model, but may be preferred in applications where computational difficulties render the Cox model impractical.

COMPETING RISKS

When a subject fails due to any of several causes, and one wants to study each of them separately, we have a problem of *competing risks*. We observe, for each individual, a survival time T and a failure type V . For each failure type, we may estimate a cause-specific hazard function

$$h_v(t) = \lim_{\Delta \rightarrow 0^+} \frac{\text{pr}(t \leq T < t + \Delta, V = v | t \leq T)}{\Delta}.$$

Unfortunately, $h_v(t)$ may not be used to estimate the individual hazard functions or survival distributions unless the event time distributions are mutually independent.^[3,11] This assumption may be plausible in some engineering applications, but is problematic in human data, where complex dependencies among competing events are likely. The *cumulative incidence function*, also known as a *subdistribution function*, is the probability of failing from failure type V before time t . It is given by

$$I_v(t) = \int_0^t h_v(u) S(u) du,$$

where $S(u)$ is the survival probability based on failure from any cause and $h_v(u)$ is the cause-specific hazard.

To illustrate these ideas, we consider the disease trajectories of men diagnosed with prostate cancer with regard to death from prostate cancer and death from other

Fig. 3 Survival and cumulative incidence estimates of the probability of death from prostate cancer and from other causes. Competing risks estimates based on cause-specific hazards are in solid black, and naive Kaplan-Meier estimates are in gray

causes.^[12,13] Fig. 3 presents, for elderly men diagnosed with poorly differentiated prostate cancer, the survival distribution of time from diagnosis to death from prostate cancer and the cumulative incidence of death from other causes. Calculation details may be found in Putter, Fiocco, and Geskus.^[14] If each of these two causes is viewed as censoring for the other, one obtains crossing curves (gray), which are not possible, as the probabilities add to more than one. For example, the naïve (gray) survival curve for death from prostate cancer incorrectly treats death from other causes as a censored observation, so that the event potentially could happen in the future. As a result, the survival probabilities are underestimated. When one correctly accounts for the competing risks, the solid black curves are obtained.

OTHER ISSUES IN SURVIVAL ANALYSIS

While right censoring is the most common form of incomplete observation in survival analysis, other kinds of censoring, such as left censoring and interval censoring, are possible. Furthermore, length-biased sampling issues arise in certain applications. For example, in some situations, such as in estimating the latency distribution in studies of AIDS, only cases that occur before a certain time are included.^[15] This is known as *right truncation*. In other applications, the data are subject to left truncation, where subjects become at risk at a known time. A thorough treatment of likelihood construction for various types of censoring and truncation may be found in Klein and Moeschberger.^[16] A general discussion of the non-parametric estimation of the survival distribution under general censoring and truncation patterns may be found in Turnbull.^[17]

Another issue that arises in some applications is clustering of the survival times. For example, one may be interested in the age of onset of a type of cancer among family members, or one may have several time measures on the same individual. These may be accommodated using a marginal model^[18] or by including a common *frailty* in the model for each cluster. Other issues arise when one's interest is in times to multiple occurrences of an event. A thorough treatment of clustering and multiple events in survival data may be found in Therneau and Grambsch.^[6]

Targeted Clinical Trials

Jen-pei Liu

Division of Biometry, Department of Agronomy, and Institute of Epidemiology, National Taiwan University, Taipei, Taiwan; and Division of Biostatistics and Bioinformatics, Institute of Population Health Sciences, National Health Research Institutes, Zhunan, Taiwan

Abstract

This entry illustrates the drawbacks of the current approach to targeted clinical trials based on the continuous data. It also discusses the EM algorithm for binary data and provides formulas for sample size determination.

Keywords: Bootstrap method; EM algorithm; Positive predictive value; Targeted clinical trials.

INTRODUCTION

For the traditional clinical trials, clinical endpoints and clinical-pathological signs or symptoms are often used as the inclusion and exclusion criteria for the intended patient population in which the new treatments are evaluated with a concurrent control. However, considerable variation exists in the responses to the new treatment even for the patients with the same diagnosis. In other words, these endpoints are not well correlated with the clinical benefits of the treatments in the patient population defined by clinical-based inclusion and exclusion criteria. Therefore current paradigm to develop and evaluate a drug or a treatment uses a shotgun approach that may not be beneficial for most of patients. One of the reasons is that the traditional inclusion/exclusion criteria do not utilize the potentially important genetic or genomic variability of the trial participants.

After completion of a human genome project, new breakthrough technology such as microarray, mRNA transcript profiling, single nucleotide polymorphism (SNP), or genome-wide association studies (GWAS) emerges. As a result, the disease targets at molecular level can be identified. Treatments specific for the molecular targets can therefore be developed for the patients who are most likely to benefit. These treatments are referred to as the targeted treatments or drugs. Unlike the shotgun blast approach, targeted therapy employed a precision guided-missile methodology to reach the molecular targets and personalized medicine finally becomes a reality.^[1,2]

Development of targeted treatments is different from the traditional approach. For a targeted therapy, one must have (i) the knowledge of the molecular targets involved in the disease pathogenesis, (ii) a device for detection of the molecular targets, and (iii) a treatment aimed for the molecular targets. Hence, development of targeted therapies involves translation from assessment of the accuracy

of diagnostic devices for the molecular targets to evaluation of the efficacy and safety of the treatment modality for the patient population with the targets. Therefore, evaluation of targeted treatments posts new challenges in clinical research and development. To address these new emergent issues, in April 2005, the U.S. Food and Drug Administration (U.S. FDA) issued the *Drug-Diagnostic Co-development Concept Paper*.^[3] The enrichment design given in Fig. 1^[4] is one of the three designs introduced in the Concept Paper for evaluation of the targeted treatments. The enrichment design consists of two phases. Phase 1 is the enrichment phase during which patients are screened by a diagnostic device for detection of the pre-defined molecular targets. Then only the patients with a positive result for the molecular target are randomized to receive either the targeted treatment or the concurrent control in Phase 2.

However, in practice, no diagnostic test is perfect with 100% positive predicted value (PPV). In addition, measures for diagnostic accuracy such as sensitivity, specificity, PPV, or negative predicted value (NPV) are in fact estimators with variability. Therefore, some of the patients enrolled in targeted clinical trials under the enrichment design might not have the specific targets and hence the treatment effects of the drug for the molecular targets could be under-estimated.^[5] Under the enrichment design, Liu and Lin^[6] and Liu et al.^[7] propose using the EM algorithm^[8–10] in conjunction with the bootstrap technique^[11] to incorporate the uncertainty on the accuracy of the diagnostic device in detection of the molecular targets for the inference of the treatment effects with binary and continuous endpoints. In the next section, we illustrate the drawbacks of the current approach based on the continuous data. The application of EM algorithm to the inference of continuous endpoints is reviewed in section “The EM Procedures.” The EM algorithm for binary data is similar

Fig. 1 Enrichment design (From Ref. [3])

and will not be given in this entry. See Liu and Lin^[6] for details. Simulation results of both continuous and binary data are given in section “Simulation Study.”^[6,7] section “Sample Size Determination” provides formulas for sample size determination with consideration of the variability of PPV. Discussion and concluding remarks are given in section “Discussion.”

CURRENT APPROACHES

For the purpose of illustration and simplicity, consider a situation where a particular molecular target involved with the pathway in pathogenesis of the disease has been identified and there is a validated diagnostic device available for detection of the identified molecular target is considered. Also suppose that a test drug for the particular molecular target is currently being developed. Under an enrichment design, one of the objectives of targeted clinical trials is to evaluate the treatment effects of the molecular targeted test treatment in the patient population truly having the molecular target. With respect to Fig. 1, we consider a two-group parallel design in which patients with a positive result by the diagnostic device are randomized in a 1:1 ratio to receive the molecular targeted test treatment (T) or a control treatment (C). We further assume that the primary efficacy endpoint is an approximately normally distributed variable, which is denoted by Y_{ij} , $j=1, \dots, n_i$; $i=T, C$. Table 1 gives the expected values of Y_{ij} by treatment and diagnostic result of the molecular target. In Table 1, μ_{T+} , μ_{C+} (μ_{T-} , μ_{C-}) are the means of test and control groups for the patients truly having (or without) the molecular target. Our parameter of interest is the treatment effects for the patients truly having the molecular target $\theta = \mu_{T+} - \mu_{C+}$. The hypothesis for detection of treatment difference in the patient population truly having the molecular target is the hypothesis of interest:

$$H_0 : \mu_{T+} - \mu_{C+} = 0 \quad \text{vs.} \quad H_a : \mu_{T+} - \mu_{C+} \neq 0 \quad (1)$$

Let $\bar{Y}_T$ and $\bar{Y}_C$ be the sample means of test and control treatments, respectively. Liu and Chow^[5] showed that

$$E(\bar{Y}_T - \bar{Y}_C) = \gamma(\mu_{T+} - \mu_{C+}) + (1 - \gamma)(\mu_{T-} - \mu_{C-}), \quad (2)$$

where γ is the PPV.

Liu and Chow^[5] indicated that the expected value of the difference in sample means consists of two parts. The first part is the treatment effects of the molecular target drug in patients with a positive diagnosis who truly have the molecular target of interest. The second part is the treatment effects of the patients with a positive diagnosis but in fact they do not have the molecular target. It follows that the difference in sample means obtained under the enrichment design for targeted clinical trials actually underestimates the true treatment effects of the molecular targeted drug in the patient population truly having the molecular target of interest if $\mu_{T+} - \mu_{C+} > \mu_{T-} - \mu_{C-}$. As it can be seen from,^[2] the bias of the difference in sample means decreases as the PPV increases. On the other hand, the PPV of a diagnostic test increases as the prevalence of the disease increases.^[12] For a disease which is highly prevalent, say greater than 10%, even with a high diagnostic accuracy of a 95% sensitivity and a 95% specificity for the diagnostic device, the PPV is only about 67.86%. It follows that the downward bias of the traditional difference in sample means could be substantial for estimation of treatment effects of the targeted drug in patients truly having the target of interest. In addition, since $\bar{Y}_T - \bar{Y}_C$ under-estimates $\mu_{T+} - \mu_{C+}$, the planned sample size may not be sufficient for achieving the desired power for detecting the true treatment effects in the patients truly having molecular target of interest. It should be emphasized that the above arguments for a downward bias also holds for the binary endpoints.^[6]

Table 1 Population Means by Treatment and Diagnosis

Positive diagnosis	True target condition	Accuracy of diagnosis	Test group	Control group	Difference
+	+	γ	μ_{T+}	μ_{C+}	$\mu_{T+} - \mu_{C+}$
+	-	$1-\gamma$	μ_{T-}	μ_{C-}	$\mu_{T-} - \mu_{C-}$

γ is the PPV.

(From Liu et al. [7]).

THE EM PROCEDURES

Although all patients randomized under the enrichment design have a positive diagnosis, the true status of the molecular target for individual patients in the targeted clinical trials is in fact unknown. Liu et al.,^[7] proposed to apply the EM algorithm for the inference of the treatment effects for the patients truly having the molecular targets. It follows that under the assumption of homogeneity of variance, Y_{ij} are independently distributed as a mixture of two normal distributions with mean μ_{i+} and μ_{i-} respectively, and a common variance σ^2 .^[12]

$$\varphi(y_{ij} | \mu_{i+}, \sigma^2)^\gamma \varphi(y_{ij} | \mu_{i-}, \sigma^2)^{1-\gamma} \quad i = T, C; j = 1, \dots, n_i, \quad (3)$$

where $\varphi(\cdot)$ denotes the density of a normal variable.

However, γ is an unknown PPV which must be estimated from the data. Therefore, the data obtained from the targeted clinical trials are incomplete because the true status of the molecular target for the patients is missing.

Let X_{ij} is the latent variable indicating the true status of the molecular target of patient j in treatment i ; $i, j = 1, \dots, n_i, i = T, C$. Under the assumption that X_{ij} are i.i.d. Bernoulli random variables with probability γ for the molecular target, the complete-data log-likelihood function for ψ is given by

$$\begin{aligned} \log L_c(\Psi) = & \sum_{j=1}^{n_T} X_{Tj} [\log \gamma + \log \varphi(y_{Tj} | \mu_{T+}, \sigma^2)] \\ & + \sum_{j=1}^{n_T} (1 - X_{Tj}) [\log(1 - \gamma) + \log \varphi(y_{Tj} | \mu_{T-}, \sigma^2)] \\ & + \sum_{j=1}^{n_C} X_{Cj} [\log \gamma + \log \varphi(y_{Cj} | \mu_{C+}, \sigma^2)] \\ & + \sum_{j=1}^{n_C} (1 - X_{Cj}) [\log(1 - \gamma) + \log \varphi(y_{Cj} | \mu_{C-}, \sigma^2)] \end{aligned} \quad (4)$$

where $\Psi = (\gamma, \mu_{T+}, \mu_{T-}, \mu_{C+}, \mu_{C-}, \sigma^2)'$, and $y_{\text{obs}} = (y_{T1}, \dots, y_{Tn_T}, y_{C1}, \dots, y_{Cn_C})$.

Liu et al.^[7] provides procedures for implementation of the EM algorithm in conjunction with the bootstrap procedure for inference of θ in the patient population truly having the molecular target.

Let $\hat{\theta}$ be the estimator for the treatment effects in the patients truly having the molecular target obtained from the EM algorithm and S_B^2 denote the estimator of the variance of $\hat{\theta}$ obtained by the bootstrap procedure. It follows that the null hypothesis is rejected in Eq. 1 at the α level if

$$t = \left| \frac{\hat{\theta}}{\sqrt{S_B^2}} \right| \geq z_{\alpha/2}, \quad (5)$$

where $z_{\alpha/2}$ is the upper $100(\alpha/2)$ percentile of a standard normal distribution.

Liu et al.^[7] showed that the corresponding $(1 - \alpha)100\%$ asymptotic confidence interval for $\theta = \mu_{T+} - \mu_{C+}$ can be constructed as

$$\hat{\theta} \pm z_{1-\alpha/2} \sqrt{S_B^2} \quad (6)$$

They also pointed out that although the assumption that $\mu_{T+} - \mu_{C+} > \mu_{T-} - \mu_{C-}$ is one of the reasons for developing the targeted treatment, this assumption is not used in the EM algorithm for estimation of θ . Hence, the inference for θ by the proposed procedure is not biased in favor of the targeted treatment.

The procedure of application of the EM algorithm to the binary endpoints under the enrichment design can be found in Liu and Lin.^[6]

SIMULATION STUDY

Extensive simulation studies for comparing the performance of the EM procedures and traditional approach in statistical inference in terms of relative bias for estimation and size and power of hypothesis testing were conducted by Liu and Lin^[6] and Liu et al.^[7] for binary and continuous endpoints respectively. Some of their results are presented below.

First, they empirically demonstrated that the standardized $\hat{\theta}$ follows a standard normal distribution. Fig. 2 presents a Q-Q plot of 5000 standardized $\hat{\theta}$ versus the standard normal deviates. This Q-Q plot is a 45-degree straight line with a p-value of 0.2 for the normality by the Kolmogorov and Smirnov test. Therefore, empirical evidence from the simulation supports the normality of $\hat{\theta}$.

For continuous endpoints, Table 2 show that the absolute relative bias of the estimator for θ by the current method ranges from 8.5% to more than 50% and it increases as the PPV decreases. On the other hand, the absolute relative bias of the estimator by the EM algorithm does not exceed 4.6% while most of them are smaller than 2%. The variability has little impact on the bias of both methods. The relative bias of the current method without consideration of the true status of molecular target can be as high as 50% when the PPV is low. Consequently, the empirical coverage probabilities of the corresponding 95% confidence interval can be as low as only 8.6% when the PPV is 50%, mean difference is 20, standard deviation is 20, and n is 100. 14.1% of the 95% confidence intervals by the current method in Table 2 exceed 0.9449. On the contrary, only 9.4% of the 64 coverage probabilities of the 95% confidence intervals by the EM method are below 0.9449. However, 62 of the 64 coverage probabilities of the 95% confidence interval constructed by the EM algorithm are above 0.94. No coverage probability of the EM method is below 0.92. Table 3 provides the absolute relative bias and coverage probabilities

Fig. 2 The Quantile-Quantile plot when the positive predicted value is 0.9, $n = 50$, and $SD = 20$ for the continuous endpoints. (From Liu et al. [7])

for the binary data. From Table 3, similar conclusion can be reached for the binary endpoints.

The empirical powers of the simulation for the continuous and binary endpoints are given respectively in Tables 4 and 5. In addition, Fig. 3 presents the power curves for a two-sided test based on the continuous endpoints when $n = 50$, $\sigma = 20$ and PPV is 0.8 while Fig. 4 provides a comparison of the power curves for the one-sided hypothesis based on binary endpoints for PPV being 0.8. In Table 4, the power of the current method is an increasing function of the PPV. For both methods, the power increases as the sample size increases. However, the simulation results clearly demonstrate that the proposed testing procedure for the treatment effects based on the EM algorithm in the patient population truly having the molecular target is uniformly more powerful than the current method as depicted in Fig. 3. Additional simulation studies also show that the impact of the heterogeneity of variances and the value of $\mu_{T+} - \mu_{C+}$ on the bias, coverage probability, size and power is inconsequential. As shown in Table 5 and Fig. 4, similar results can be found for the binary endpoints.

SAMPLE SIZE DETERMINATION

The required sample size with incorporation of inaccuracy and uncertainty of diagnostic accuracy to achieve $1 - \beta$ power for rejecting the null hypothesis^[1] at the α significance level for a two-tailed alternative is given as

$$n = \frac{(Z_{1-\alpha/2} + Z_{1-\beta})^2 \{2\sigma^2 + \gamma(1-\gamma)[(\mu_{T+} - \mu_{T-})^2 + (\mu_{C+} - \mu_{C-})^2]\}}{(\mu_{T+} - \mu_{C+})^2} \quad (7)$$

Liu et al.^[7] also conducted a small simulation to empirically investigate whether the proposed sample size can provide sufficient power. The results are reproduced in Table 6. From Table 6, the empirical power provided by the required sample size of the proposed EM method ranges from 0.7898 to 0.8076. On the other hand, the empirical power of the sample size for the unpaired two-sample t -test ranges from 0.4938–0.7174. Although the required sample sizes of the proposed EM procedure and the unpaired two-sample t -test are approximately the same, because the traditional unpaired two-sample t -test does not consider inaccuracy and uncertainty of the accuracy estimate for the diagnostic device, as demonstrated in Table 6, it fails to provide sufficient power. On the contrary, our proposed EM method can provide sufficient power at our targeted value of 80%. The simulation results provided in Table 6 are also consistent with the empirical powers given in Table 4. For example, in Table 6, when $\sigma = 20$, $\mu_{T+} - \mu_{C+} = 8$ and $PPV = 0.7$, the sample sizes of both methods are around 100 with a power 0.4938 and 0.8038, respectively, for the unpaired two-sample t -test and the proposed EM method. From Table 4, the empirical power for $\sigma = 20$, $\mu_{T+} - \mu_{C+} = 8$, $n = 100$ and $PPV = 0.7$ is 0.4866 and 0.7876, respectively, for the unpaired two-sample t -test and the proposed EM method.

DISCUSSION

Under the enrichment design, all patients must have a positive diagnosis for the molecular targets by the diagnostic device to be randomized to receive either the molecular targeted drug or the control treatment in the

targeted clinical trials. However, because no diagnostic device is perfect with 100% PPV, some patients with a positive result may in fact not have the molecular target. As a result, the current estimation method may produce a biased estimator for the treatment effects of the molecular targeted test drug in the patients truly having the molecular target. EM algorithm can be applied to incorporate information of the PPV for inference of the treatment effects in the patient population truly having with the

molecular target. Simulation results clearly show not only that the EM estimation method is unbiased and can provide sufficient coverage probability but also that the EM testing procedure can adequately control the type I error rate at the nominal level and is uniformly more powerful than the current method. Liu et al.^[7] has suggested that the traditional sample means, $\bar{Y}_T$ and $\bar{Y}_C$, of the test and control treatments are reasonable initial values for the proposed method.

(From Liu and Lin [6]).

In this entry, we have only considered continuous and binary endpoints. However, the inferential procedures for the treatment effects based on the censored endpoints for the molecularly targeted test drug in the patients truly having the

molecular target require further research. Bayesian method is another approach to incorporating the uncertainty in accuracy of the diagnostic device for the molecular target into the inference of the treatment effects of the targeted drug.

Abstract

This entry reviews the most commonly used statistical methods designed for testing against qualitative interaction by summarizing the testing procedures and providing tables for illustration of each. It also discusses the advantages and disadvantages of each method in terms of applicability.

INTRODUCTION

In clinical trials involving comparison of two treatment groups, often investigators wish to know whether and how the between-treatment difference varies across patient subsets, which may be defined by prognostic factors such as age, gender, disease severity status, or clinical centers. This leads to the consideration of the treatment-by-patient-subset interaction.

While interaction may exist in numerous ways and with various patterns, Peto^[1] first distinguished *qualitative interaction* from *quantitative interaction*. A quantitative interaction, which is frequently referred to as noncross-over interaction, occurs if the treatment effect varies in magnitude but not in direction across all patient subsets; qualitative interaction, or crossover interaction, refers to the situation where the between-treatment difference changes direction among patient subsets. The existence of quantitative interaction is subject to the measurement scale and is relatively less problematic in terms of its clinical implications, whereas the presence of qualitative interaction cannot be eliminated by transformations and often has therapeutic significance. Therefore, it is important to determine whether apparent crossovers in treatment effect among patient subsets are mainly attributed to chance of variation.

In this article, we review the most commonly used statistical methods designed for testing against qualitative interaction. Our main focus is on the following three methods: the likelihood ratio test (LRT) proposed by Gail and Simon (GS),^[2] the range test considered by Piantadosi and Gail,^[3] and the multiple comparison testing procedure suggested by Pan and Wolfe.^[4] We summarize each testing procedure by outlining the authors' formulation of the test statistics and providing tables of critical values. We also discuss the advantages and pitfalls of each method in terms of power and applicability in practice. In addition,

some follow-up variations and enhancements available in the literature are briefly mentioned as well.

TESTS FOR QUALITATIVE INTERACTION

Assume that two treatments are being compared across I patient subsets. Let μ_{ij} be the expected response of the j th treatment in the i th subset where $j = 1, 2$ and $\delta_i = \mu_{i1} - \mu_{i2}$ be the treatment effect in the i th subset for $i = 1, \dots, I$. As pointed out by Russek-Cohen and Simon,^[6] μ_{ij} can be thought of as the log odds in logistic regression, and hence δ_i is the log odds ratio for the i th subset. When a Cox proportional hazards model is used to model survival times, μ_{ij} can be thought of as the logarithm of hazard, and hence δ_i is the logarithm of relative risk between the two treatment groups for the i th patient subset.

Let D_i be the estimated treatment effect for the i th patient subset. We assume that D_i 's are independent and normally distributed with mean δ_i and known variance $\sigma_i^2 = w_i \sigma^2$, where w_i is a known constant that depends on the sample size and σ^2 is typically the population error variance. Note that this formulation is generally enough because asymptotic normality broadly holds for various estimators. To test for no qualitative interaction, the null hypothesis is that δ_i 's are all non-negative or all nonpositive.

Likelihood Ratio Test

The LRT proposed by Gail and Simon^[2] is the most influential and inspiring contribution in testing for qualitative interaction. To illustrate, let $\delta = (\delta_1, \dots, \delta_I)'$, $O^+ = \{\delta : \delta_i \geq 0, \text{all } i\}$, and $O^- = \{\delta : \delta_i \leq 0, \text{all } i\}$. Therefore, we wish to test

$$H_0 : \delta \in O^+ \cup O^- \text{ vs. } H_1 : \text{not } H_0 \quad (1)$$

The likelihood ratio for this hypothesis is

$$\frac{\max_{\delta \in O^+ \cup O^-} \exp \sum_{i=1}^I \left\{ -(D_i - \delta_i)^2 / (2w_i \sigma^2) \right\}}{\max_{\delta} \exp \sum_{i=1}^I \left\{ -(D_i - \delta_i)^2 / (2w_i \sigma^2) \right\}}$$

The denominator reaches the maximum at $D_i = \delta_i$ and the LRT is thus

$$\max_{\delta \in O^+ \cup O^-} \exp \sum_{i=1}^I \left[-(D_i - \delta_i)^2 / w_i \right] < k \cdot \sigma^2$$

where the constant k is chosen such that the probability of rejecting the null hypothesis does not exceed the significant level α . The preceding maximization problem can be simplified further so that Gail and Simon's test rejects the null hypothesis of no qualitative interaction if both

$$Q^+ = \sum_{i=1}^I \left\{ D_i^2 / w_i \right\} I(D_i > 0) > c \cdot \sigma^2$$

and

$$Q^- = \sum_{i=1}^I \left\{ D_i^2 / w_i \right\} I(D_i < 0) > c \cdot \sigma^2$$

where $I(\cdot)$ is the indicator function and $c = -2\log(k)$. The quantities Q^+ and Q^- are the minimum values of $\sum_{i=1}^I [(D_i - \delta_i)^2 / w_i]$ over O^+ and O^- , respectively. Therefore, the LRT can be simply expressed as

$$\min(Q^+, Q^-) / \sigma^2 > c \quad (2)$$

As shown in GS, the critical value c is determined by the following equation:

$$\sum_{j=1}^{I-1} B(j; n = I - 1, p = 0.5) \{1 - \chi_j^2(c)\} = \alpha \quad (3)$$

where $B(j; n, p)$ is the binomial mass function with parameters n and p ; $\chi_j^2(\cdot)$ is the cumulative distribution function (cdf) of the chi-square distribution with j degrees of freedom. Gail and Simon gave a table, as reproduced in Table 1, for critical values c at significance level 0.001, 0.025, 0.05, 0.10, and 0.20 for the LRT. The above method can also be used to test the hypothesis that all treatment differences are greater (or less) than a prespecified threshold d by simply applying the method to the translated estimate $D_i - d$, which appears to be a useful and practical extension.

The variance σ_i^2 for each patient subset is assumed known in GS. Even though the LRT procedures are valid for large samples if consistent estimators of σ^2 are employed instead, Silvapulle^[7] noticed that the asymptotic critical values given in Table 1 might not be appropriate for small samples, which motivated him to derive the exact finite sample results.

Table 1 Critical Values c for the LRT $\min(Q^+, Q^-) / \sigma^2 > c$

(From Ref. [2].)

Let S^2 be an estimate of σ^2 such that $\nu S^2 / \sigma^2 \sim \chi_\nu^2$ and S^2 is independent of D_i 's. Typically, S^2 can be chosen as the usual mean square error. Silvapulle^[7] constructed a test statistic

$$F_Q = \frac{\min(Q^+, Q^-)}{S^2} \quad (4)$$

which resembles the usual F -ratio. The exact α -level critical value c for the test with unknown variance is given by the solution of the following equation:

$$\sum_{j=1}^{I-1} B(j; n = I - 1, p = 0.5) \Pr\{F_{j,\nu} > c/j\} = \alpha \quad (5)$$

where $B(j; n = I - 1, p = 0.5)$ is the binomial probability of j successes out of $I - 1$ trials with a probability of success 0.5. $F_{j,\nu}$ is the F distribution with degrees of freedom j and ν . If the sample value of FQ is f_q , then the exact p -value is

$$\sum_{j=1}^{I-1} B(j; n = I - 1, p = 0.5) \Pr\{F_{j,\nu} > f_q/j\} \quad (6)$$

Silvapulle^[7] provided a table (Table 2) that covers a wide range of possible values of ν , the total patient subsets I , and selected sets of critical values that is useful for practical purposes.

The LRT for the qualitative interaction can be extended to the situation where between-treatment difference D_i 's are dependent and have an arbitrary covariance matrix Σ . This typically happens when treatment effect is estimated with respect to some extraneous covariates. The test rejects H_0 if both

^aThe observations are assumed to be independent and normal with a common variance.

^bThe parameter ν is the degrees of freedom for the estimate of error.

^cThe critical values in the last line corresponding to d.f. = ∞ are the same as those in Ref. [2]. (From Ref. [7].)

$$Q^+ = \min_{\Delta \in O^+} [(D - \delta)' \Sigma^{-1} (D - \delta)] > c$$

and

$$Q^- = \min_{\Delta \in O^-} [(D - \delta)' \Sigma^{-1} (D - \delta)] > c$$

The difficulty involved in the above minimization problem is substantial. It should be solved by quadratic programming,^[8] and the critical value c usually depends on the covariance matrix Σ . This idea has been further explored by Russek-Cohen and Simon^[6] in their qualitative interaction tests for multifactor studies. Various topics concerning the hypothesis to test for normal means based on quadratic form under the constraints of linear inequalities or equalities can be found in Refs. ^[6,9–11]

The statistical properties of the LRT were discussed by Zelterman.^[12] Let $d(\mathbf{D})$, where $\mathbf{D} = (D_1, \dots, D_I)'$, denote a decision rule for testing H_0 vs. H_1 such that one rejects H_0 if $d(\mathbf{D}) = 1$ and cannot reject H_0 if $d(\mathbf{D}) = 0$. Since the labels 1, 2, ..., I can be assigned arbitrarily, the decision rule $d(\mathbf{D})$ is invariant under any permutation of the elements of $\mathbf{D}$. Furthermore, this decision rule is invariant if signs of all D_i 's are changed simultaneously. Zelterman^[12] also pointed out that the vector of true mean difference

$\delta = \mathbf{0}$ poses the most difficult practical situation and is generally where the LRT tends to have the least power and the largest bias.

Silvapulle^[7] modified the LRT based on M -estimators in order to achieve robust power against long-tailed error distributions. In addition, Zelterman and Kershner^[13] and Berger^[11] each introduced a uniformly more powerful test for the qualitative interaction in the case of two patient subsets by augmenting the critical region of the GS test with disjoint regions in the sample space. Nevertheless, Russek-Cohen and Simon^[6] commented that “these tests have some nonintuitive properties and would not be accepted by nonstatisticians.”

The Range Test

Piantadosi and Gail^[3] proposed a test procedure for detecting the qualitative interaction based on the range test. They compared the power of the range test with that of the LRT developed by Gail and Simon.^[2] The range test rejects H_0 at a level α if both

$$\max_{1 \leq i \leq I} \{D_i / \sigma_i\} > C_{2\alpha} \quad \text{and} \quad \min_{1 \leq i \leq I} \{D_i / \sigma_i\} < -C_{2\alpha} \quad (7)$$

where $C_2\alpha$ is the critical value corresponding to the test level α . Table 3 provides the critical values for a two-sided test with respect to various numbers of subsets and test levels.

The above method can be conveniently adopted for one-sided hypotheses, e.g., $H_{01}: \Delta \in O^+$, which intends to test the “better” treatment. For the one-sided test, one rejects the null hypothesis H_{01} if $\min\{D_i/\sigma_i\} < -C_{1\alpha}$. The critical value for situations with I subsets is equal to the entry $I+1$ in Table 3. That is, $-C_{1\alpha}$ for I subsets equals $-C_{2\alpha}$ for $I+1$ subsets.

Piantadosi and Gail^[3] compared the power of the LRT with the power of the range test. To this end, they generated independent normal variates D_i for $i = 1, 2, \dots, I$ with mean δ_i and variance 1 from the uniform distribution using the Box–Muller^[14] method. The McNemar^[15] procedure was used to compare the LRT with the range test for the significance of differences in proportions from the matched samples. It was found through simulations that the range test has more power than the LRT when the new treatment is harmful only in very few subsets in terms of δ_i 's, while the LRT often has more power when the new treatment is harmful in several subsets in terms of δ_i 's. Pan and Wolfe^[5] reached the conclusion that the power of the range test has characteristics similar to those of the LRT.

Test Procedure Based on Simultaneous Inference

In addition to the testing procedures based on the likelihood ratio and the range test, Pan and Wolfe^[4] proposed a procedure to test for qualitative interaction based on simultaneous confidence intervals.

Since a small directional change in treatment differences across patient subsets may not have practical importance, Pan and Wolfe^[4] suggested distinguishing *severe* qualitative interaction from *slight* qualitative interaction. Correspondingly, they introduced a predetermined margin $d > 0$ to divide a clinically insignificant treatment effect from a clinically significant treatment effect. And they modified the hypotheses for testing no qualitative interaction as follows:

$$H_0(d): \{I \text{ of } \delta_i > -d \text{ or } I \text{ of } \delta_i < d \text{ for } 1 \leq i \leq I\}$$

$$H_1(d): \{\text{at least one } \delta_i < -d \text{ and one } \delta_j > d,$$

$$\text{where } 1 < i \neq j \leq I\} \quad (8)$$

Clearly, the margin d depends on the nature and objective of the trial. Often, it has clinical implications and should be predetermined based on the relevant clinical criteria. To draw a statistical inference on the qualitative interaction, they proposed the following test procedure $C(d)$, which is based on simultaneous z -intervals.

Table 3 Critical Values $C_2\alpha$ for the Two-Sided Range Test

30	2.42	2.68	2.92	3.13	3.98

(From Ref. [3].)

1. Compute the joint confidence level $P_E = 2(1 - \alpha)^{1/(I-1)} - 1$
2. Construct a z -confidence interval (L_i, U_i) with confidence level P_E for each patient subset i , $i = 1, \dots, I$, i.e.,

$$(L_i, U_i) = \left[D_i - z \left(\frac{1 - P_E}{2} \right) \sigma_i, D_i + z \left(\frac{1 - P_E}{2} \right) \sigma_i \right], \quad 1 \leq i \leq I \quad (9)$$

where $z(\gamma)$ is the upper γ critical point of a standard normal distribution.

3. Reject null hypothesis $H_0(d)$ if there is a pair $1 \leq i \neq j \leq I$ such that

$$U_i < -d \text{ and } L_j > d \quad (10)$$

Otherwise, do not reject $H_0(d)$.

The testing procedure is easy to implement, and it is essentially a Bonferroni approach. It should be noted that the test procedure could be very conservative, especially when I , the number of patient subsets, is quite large. Pan and Wolfe tabulated simultaneous confidence coefficients for the calculations of the confidence intervals (Table 4). They also showed that the proposed test has a size not greater than α for any given value of d . That is,

$$\sup_{H(d, \delta)} \Pr[C(d) \text{ rejects } H_0] \leq \alpha$$

Table 4 Confidence Coefficients Used to Construct $C(d)$

30	0.98467	0.99275	0.99647	0.99825	0.99993

(From Ref. [4].)

An additional feature is that the power function is explicitly available:

$$\begin{aligned}
& 1 - \prod_{i=1}^I \Phi \left\{ \frac{d - \delta_i}{\sigma_i} - z \left[1 - (1 - \alpha)^{1/(I-1)} \right] \right\} \\
& - \prod_{i=1}^I \Phi \left\{ \frac{d + \delta_i}{\sigma_i} - z \left[1 - (1 - \alpha)^{1/(I-1)} \right] \right\} \\
& + \prod_{i=1}^I \left[\Phi \left\{ \frac{d - \delta_i}{\sigma_i} - z \left[1 - (1 - \alpha)^{1/(I-1)} \right] \right\} \right. \\
& \left. - \Phi \left\{ \frac{-d - \delta_i}{\sigma_i} - z \left[1 - (1 - \alpha)^{1/(I-1)} \right] \right\} \right] \quad (11)
\end{aligned}$$

Note that the conclusion of Pan and Wolfe's^[4] method depends on whether or not there is a pair of confidence intervals lying on both sides of the interval $(-d, d)$, which renders the procedure more suitable for analysis involving a small or a medium number of patient subsets. For example, consider an equivalence trial conducted in a large number of centers. The conclusion regarding the existence of qualitative interaction may be dramatically affected by the inclusion of a couple of centers that happen to yield outlying treatment effect estimates on both sides of the equivalence margins. In order to circumvent this difficulty, Yan^[16] modified the testing procedure by Pan and Wolfe^[4] so that the total number of patient subsets is taken into account in assessing qualitative treatment-by-center interaction.

The method proposed by Yan^[16] introduces a tuning parameter k to quantify the number of outlying centers that is tolerable. The tuning parameter k is imbedded into the hypothesis as follows:

$$H_0(d, k) : \{I - k \text{ of } \delta_i > -d\} \text{ or}$$

$$\{I - k \text{ of } \delta_i < d\}$$

$$H_1(d, k) : \{\text{at least } k + 1 \text{ of } \delta_i < -d$$

$$\text{and another } k + 1 \text{ of } \delta_i > d\} \quad (12)$$

Note that the null hypothesis above is identical to that of Pan and Wolfe's method when $k = 0$. However, the null hypothesis above allows for $k > 0$. This provides the flexibility for selection of a fixed number of centers whose confidence intervals on the between-treatment difference are on both outside of the equivalence margins without indicating qualitative interaction. In fact, k can be considered as a tuning parameter to quantify the tolerance level of the qualitative interaction and should be carefully predetermined based on both the nature of the clinical trial and the total number of investigational centers. This needs to be paid substantial attention in order to prevent the proposed testing procedure from being rendered suspect due to the selection of a value of k . Yan^[16] recommended that k should be less than 5% of the total number of the centers when the design is balanced. Moreover, for an unbalanced design, it is necessary to use a sample size weighting scheme to calculate the simultaneous confidence intervals. Since large centers would be more informative than small

centers, if the confidence intervals on δ_i 's for large centers are completely on both outsides of the equivalence margins, the qualitative interaction may not be negligible.

Based on the hypothesis above, qualitative interaction is confirmed if at least $k + 1$ confidence intervals of the between-treatment difference are entirely above the upper equivalence margin d and at least another $k + 1$ confidence intervals of the between-treatment difference are completely below the lower equivalence margin $-d$. Because of the introduction of the tuning parameter k , the construction of I simultaneous confidence intervals should be based on a confidence level of

$$P_E = 2 \cdot (1 - \alpha)^{1/(I-k-1)} - 1$$

as derived in Ref. [16]. The size of the test is shown to be less than α . Therefore, the introduction of k allows for drawing a valid statistical conclusion without subjectively removing those “extremely bad” centers. Moreover, Yan^[16] also gave the explicit power function:

$$\begin{aligned} & 1 - \prod_{i \in A} \Phi \left[\frac{d + \delta_i}{\sigma_i} + z \left(\frac{1 - P_E}{2} \right) \right] \\ & \times \prod_{j = j_1, j_2, \dots, j_l \in A^c} \Phi^{\omega(j)} \left[\frac{-d - \delta_j}{\sigma_j} - z \left(\frac{1 - P_E}{2} \right) \right] \\ & - \prod_{i \in B} \Phi \left[\frac{d - \delta_i}{\sigma_i} + z \left(\frac{1 - P_E}{2} \right) \right] \\ & \times \prod_{j = j'_1, j'_2, \dots, j'_m \in B^c} \Phi^{\omega(j)} \left[\frac{-d + \delta_j}{\sigma_j} - z \left(\frac{1 - P_E}{2} \right) \right] \\ & + \prod_{i \in C} \left\{ \Phi \left[\frac{d - \delta_i}{\sigma_i} + z \left(\frac{1 - P_E}{2} \right) \right] \right. \\ & \left. - \Phi \left[\frac{-d - \delta_i}{\sigma_i} - z \left(\frac{1 - P_E}{2} \right) \right] \right\} \\ & \times \prod_{j = j_1, j_2, \dots, j_l \in A^c} \Phi^{\omega(j)} \left[\frac{-d - \delta_j}{\sigma_j} - z \left(\frac{1 - P_E}{2} \right) \right] \\ & \times \prod_{j = j'_1, j'_2, \dots, j'_m \in B^c} \Phi^{\omega(j)} \left[\frac{-d + \delta_j}{\sigma_j} - z \left(\frac{1 - P_E}{2} \right) \right] \end{aligned} \quad (13)$$

where the set A is the index set for the confidence intervals (L_i, U_i) whose upper bound $U_i \geq -d$, i.e., $A = \{i \mid U_i \geq -d, \text{ for all } i\}$; the set B is the index set for the confidence intervals (L_i, U_i) whose lower bounds $L_i \leq d$, i.e., $B = \{i \mid L_i \leq d, \text{ for all } i\}$; and the sets A^c and B^c are the complementary sets of A and B , respectively. Also, $\omega(j)$ is an indicator function for the j th confidence interval, i.e., $\omega(j) = 1$ if index j is in set A^c or set B^c , otherwise, $\omega(j) = 0$; $z(\gamma)$ is the

upper $1 - \gamma$ quantile of the standard normal distribution; and $\gamma = (1 - P_E)/2 = 1 - (1 - \alpha)^{1/(I-k-1)}$.

CONCLUSIONS

Evaluation of treatment effect among patient subsets induced by some prognostic factors is of practical importance. In particular, when the prognostic factor is clinical center, the qualitative treatment-by-center interaction is typically of interest. We have reviewed three standard statistical methods designed for detecting the qualitative interaction: the test based on likelihood ratio, the range test, and simultaneous confidence intervals. These methods have received favorable coverage in the literature and have been widely used in practice.

Three sets of test hypotheses are introduced in (1), (8), and (12). For the evidence of no qualitative interaction, the original GS hypothesis (1) defines the situation that all between-treatment differences are of the same sign. Hypothesis (8) focuses on the situation where the between-treatment differences are all above a prespecified clinical insignificance lower margin $-d$ or are all below a prespecified clinical insignificance upper margin d . Hypothesis (12) emphasizes the situation where $I - k$ of the between-treatment differences are all above $-d$ or are all below d , accounting for the total number of patient subsets. Hypotheses (8) and (12) are suitable for a balanced design. For an unbalanced design, a sample size weighting scheme should be used. Besides the test hypotheses (1), (8), and (12), other hypothesis formulations are also arguably more reasonable, and details can be found in Ref. [17].

There are several issues related to the test for the qualitative interaction. In the review, we have focused on two-sided hypotheses concerning the comparison of two treatments among all patient subsets. However, these testing procedures are readily modified to incorporate one-sided hypotheses. In this situation, we test how consistent the advantage of the treatment over the control is among all patient subsets. This is of central interest in noninferiority trials. Secondly, most existing methods concern situations where prespecified patient subsets are disjoint. This is a limitation; however, there are good practical reasons for doing so.^[2] In most applications, one can assume independence among patient subsets to simplify the testing procedure. Nevertheless, it should be noted that the testing procedure could be more complicated when patient subsets are not disjoint. Thirdly, the power for detecting the qualitative interaction is always challenging. This is mainly because, given the general problem setting, only summary information for each patient subset is used. This results in a very limited sample size (i.e., number of subsets), which directly leads to reduction in statistical power for any proposed test.

In addition to the testing procedures discussed, several other methods are noteworthy. Shuster and Van Eys^[18] considered the evaluation of qualitative interaction

between treatment and a continuous covariate, say x , with an effort to divide the values of x into three sets where treatment A is superior, treatment B is superior, and neither is superior. Azzalini and Cox^[19] presented a test for qualitative interaction in the two-way analysis of variance setting under the assumption of no main effects, an assumption that is “unlikely to be true in practice” as indicated by Russek-Cohen and Simon.^[6] In addition, Ciminera et al.^[20] proposed a “pushback” procedure for checking qualitative treatment-by-center interaction. Their procedure first “pushes back” the standardized deviations of D_i ’s from a reference value, e.g., the median, by appropriate amounts and then restores them to the original scale. The appearance of opposite signs among the restored deviations is then taken as substantial evidence of qualitative interaction. Since no joint significance level is justified, their procedure may better serve as a tool for retrospectively detecting qualitative interaction.

Therapeutic Equivalence

Jen-pei Liu

Division of Biometry, Department of Agronomy, and Institute of Epidemiology, National Taiwan University, Taipei, Taiwan; and Division of Biostatistics and Bioinformatics, Institute of Population Health Sciences, National Health Research Institutes, Zhunan, Taiwan

Abstract

Traditionally, most of the trials conducted by the pharmaceutical industry during phases II and III are aimed at obtaining the necessary evidence for establishing the effectiveness and safety of the new therapeutic entity under development. This entry is focused on the process of equivalence trials and recent developments in hypothesis testing in terms of determining therapeutic equivalence.

Keywords: Active control; Equivalence limit; Non-inferiority; Sample size.

INTRODUCTION

Traditionally, most of the trials conducted by the pharmaceutical industry during phases II and III are aimed at obtaining the necessary evidence for establishing the effectiveness and safety of the new therapeutic entity under development. Consequently, these trials are, in general, the superiority trials in which the primary goal is to demonstrate the better efficacy of the treatment against the concurrent placebo control. However, as innovative drugs become available for the treatment of a number of diseases, attention has focused on searching for new therapeutic modalities to compete with the standard products on the market. These new products may offer some specific advantages over the standard drug, including a better safety profile, improvement on the quality of life, an easy administration route, a short duration of treatment, and, most importantly, reduction of cost. As a result, because of these additional benefits, the new drug is not required to show its superior efficacy over the standard drug but to prove that its effectiveness is no worse than that of the standard. In other words, the sponsors have to provide the evidence that the test product is at least as efficacious as the standard. This concept of demonstration of no worse efficacy but with some specific added values provided by the new treatment is referred to as therapeutic equivalence. As a result, studies with objectives for therapeutic equivalence are then called the non-inferiority trials. Because therapeutic equivalence only requires establishing that efficacy of the new treatment is no worse than that of the standard, it is referred to as one-sided equivalence.

On the other hand, after the patent of an innovative product expires, other pharmaceutical companies can manufacture generic copies under the Drug Price Competition and Patent Term Restoration Act passed in 1984 through the Abbreviated New Drug Application

(ANDA). The generic copies must be demonstrated to be equivalent to the innovative product based on the pharmacokinetic (PK) responses such as the area under plasma concentration-time curve (AUC) or peak concentration ($C_{\max}$) obtained from bioequivalence studies.^[1] According to the current requirement,^[2] a generic copy is claimed to be bioequivalent to the market reference product if the average bioavailability of the generic product is neither too high nor too low as compared to that of the reference product. As a result, bioequivalence emphasizes two-sided equivalence. Bioequivalence includes average bioequivalence, population bioequivalence, and individual bioequivalence that are reviewed and discussed in details in the entry Equivalence Trials.

ONE-SIDED EQUIVALENCE AND NON-INFERIORITY TRIALS

Let μ_T and μ_S be the average efficacy of the test and the standard drugs, respectively, and let a large value in average imply a better efficacy. For a superiority trial, investigators are interested in detecting whether a difference in efficacy exists between the test and the standard drugs. As a result, this question can be answered by the following formulation of hypotheses:

$$H_0 : \mu_T = \mu_S \text{ vs. } H_a : \mu_T \neq \mu_S \quad (1)$$

The alternative hypothesis in Eq. (1) is in the form of a two-sided hypothesis. Others^[3] argue that for a superiority trial, the alternative should be formulated as a one-sided hypothesis:

$$H_a : \mu_T > \mu_S \quad (2)$$

For a detailed discussion and debate of one-sided versus two-sided hypotheses from the perspectives of both the pharmaceutical industry and the regulatory authority, see Koch,^[4] Dubey,^[5] and Chow and Liu.^[6]

If the null hypothesis in Eq. (1) is rejected at the α significance level, then depending upon the alternative in Eqs. (1) or (2), either the existence of a true difference in average efficacy between the test and the standard drugs or a better average efficacy provided by the test drug can be proven at the α significance level. However, when the null hypothesis that $\mu_T = \mu_S$ is not rejected, the conclusion of the trial should never be that the average efficacy of the test drug is the same as that of the standard because the null hypothesis can never be proven in a trial.^[7] In addition, a statistically non-significant, yet clinically meaningful, difference may result from a poorly conducted trial that provides variable data and a large experimental error. On the other hand, well-designed and carefully executed trials generate reliable data to provide estimates of treatment effects with high accuracy and precision. However, less variable data of good quality is able to declare a small difference of no clinical significance to be statistically significant and to conclude that the test and the standard drugs have different average efficacy. The reason for this paradox is that the formulation of hypotheses in Eq. (1) is the wrong hypothesis for evaluation of one-sided equivalence in a non-inferiority trial.

The correct formulation for the hypotheses of interest will be the one-sided hypothesis to test whether the test drug is at least as effective as the standard:^[8–11]

$$H_0 : \mu_T - \mu_S \leq L \text{ vs. } H_a : \mu_T - \mu_S > L \quad (3)$$

where L is the maximum allowable limit of no clinical significance.

The objective of the trial is to prove that the test drug is no worse than the standard treatment—although the average efficacy of the test drug is below that of the standard, but within a range of no clinical significance. It follows that this statement is formulated as the alternative hypothesis in Eq. (3). The equivalence limit L in Eq. (3) is usually a small negative number to define the lower limit for a range of no clinical significance or better efficacy. For the continuous endpoints from a two-group parallel design comparing a test drug with n_T patients to the standard drug with n_S patients, let $\bar{Y}_T$ and $\bar{Y}_S$ be the observed means of the test and the standard drugs, respectively, and let s^2 be the pooled variance. The null hypothesis of Eq. (7) is rejected, and the test drug is then claimed to be at least as efficacious as the standard at the pre-specified α nominal level of significance if

$$T = (\bar{Y}_T - \bar{Y}_S - L) / s \sqrt{1/n_T + 1/n_S} > z(\alpha) \quad (4)$$

where $z(\alpha)$ is the α th upper quantile of the standard normal distribution.

Assessment of equivalence is not only a testing procedure but also an estimation problem. Many have advocated the use of confidence interval for evaluation of both types of equivalence.^[1,7,12–15] For one-sided equivalence, the same conclusion can be reached if the lower $(1 - \alpha)100\%$ confidence limit

$$(\bar{Y}_T - \bar{Y}_S) - z(\alpha)(s\sqrt{1/n_T + 1/n_S}) \quad (5)$$

is larger than the lower equivalence limit L . The confidence interval approach is more appealing than the testing hypothesis procedure. It not only provides the magnitude and range of the average difference between the two treatments but also offers the investigators or readers an opportunity to make their own judgment about whether the test and the standard drugs are equivalent. For a two-group parallel design with equal allocation, the same size per group required to achieve a $(1 - \beta)$ power at α the significance level for non-inferiority trial with respect to hypothesis 3 can be estimated by the following formula:

$$n = 2[\sigma^2/(\delta + L)^2][z(\alpha) + z(\beta)]^2 \quad (6)$$

where $\delta = \mu_T - \mu_S > L$ is the assumed true difference in average efficacy between the test and the standard drugs, σ^2 is the common variance, and $z(\beta)$ is the upper β th quantile of the standard normal distribution.

From Eq. (6), the sample size is a decreasing function of the true unknown difference $\mu_T - \mu_S$. When $\delta = 0$, formula 6 reduces to

$$n = 2[\sigma/L]^2[z(\alpha) + z(\beta)]^2$$

For the sample size for evaluation of two-sided therapeutic equivalence, see Liu;^[16] and for bioequivalence under a standard two-sequence, two-period crossover design, see Liu and Chow.^[17] Blackwelder^[9] has suggested the following procedure for evaluation of one-sided equivalence based on binary endpoints from a two-group parallel trial: The corresponding hypotheses are given below as

$$H_0 : P_T - P_S \leq L \text{ vs. } H_a : P_T - P_S > L \quad (7)$$

where P_T and P_S are the response rates of the test and the standard treatments. Let p_T and p_S be the corresponding observed response rates. The null hypothesis of Eq. 7 is rejected, and the test drug is then claimed to be no worse than the standard at the pre-specified nominal α level of significance if

$$Z = (p_T - p_S - L)/SE > z(\alpha) \quad (8)$$

where $SE^2 = \{[p_T(1 - p_T)/n_T] + [p_S(1 - p_S)/n_S]\}$. The corresponding lower $(1 - \alpha)100\%$ confidence limit and sample-size estimation formula are given respectively as

$$(p_T - p_S) - z(\alpha)SE$$

and

$$n = \left\{ SE^2 / [(P_T - P_S) + L]^2 \right\} \{ z(\alpha) + z(\beta) \}^2$$

Durrleman and Simon^[7] and Jennison and Turnbull^[18] have demonstrated the use of repeated confidence intervals for evaluation of equivalence in a sequential testing manner. Wellek^[19] has proposed a log-rank test for assessment of equivalence between two survival functions.

ACTIVE CONTROL EQUIVALENCE TRIALS

Because non-inferiority trials try to demonstrate that the efficacy of the test drug is no worse than that of the concurrent standard competitor, they are also referred to as active control equivalence trials (ACETs). Issues regarding ACET are thoroughly documented, see, for example, Makuch and Johnson,^[14] Leber,^[20] Senn,^[21] Fleming,^[22] Temple and Ellenburg,^[23] Ellenburg and Temple,^[24] Siegel,^[25] and Fisher et al.^[26] Table 1 provides a set of criteria for evaluating quality of ACETs suggested by Kirshner.^[27] The most critical criterion is the effectiveness of the standard drug. When the test and the standard drugs are therapeutically equivalent, they can be both efficacious or both inefficacious. Leber^[20] provides an excellent illustration of the danger for inference of the results from an active control trial. A series of six trials were conducted to investigate the effectiveness of a new drug for treatment of endogenous depression with an active control imipramine, considered as a standard antidepressant. The results are given in Table 2. If we only look at the comparisons in reduction of the Hamilton depression scale (HAM-D) from baseline between the test drug and the imipramine, both drugs produce a clinically meaningful mean reduction in

HAM-D. However, the null hypothesis of equal reduction in HAM-D is not rejected at the 5% significance level, and the power to detect a 30% difference is quite low. It seems that the test drug and the imipramine have similar efficacy. On the other hand, from Table 2, except for Study V311, the mean reduction in HAM-D for the placebo is also numerically similar to those of the test drug and the imipramine. In other words, except for V311, one cannot reject the null hypothesis that the mean reductions from baseline in HAM-D of both active treatments equal to that of the placebo; hence, both test drugs and imipramine are ineffective as compared to the placebo.

If a concurrent placebo control were not included in these six studies, the test drug would have been claimed effective based on the conjecture that the test drug and the imipramine have similar efficacy. This example illustrates the importance of the inclusion of a concurrent placebo control in an ACET unless the active standard has been proven to be efficacious in adequate well-controlled studies against a concurrent control. As a result, Huque and Dubey,^[28] Pledger and Hall,^[29] ICH,^[10] and Chow and Liu^[6] have recommended that an ACET include three treatments: a test drug, an active standard, and a placebo concurrent control. In addition to evaluation of therapeutic equivalence between the test and the standard drugs, an ACET is required to provide internal validity by verifying effectiveness of both test and standard drugs against the concurrent placebo. As a result, the following hypotheses are formulated to evaluate these two major objectives:

$$\begin{aligned} H_0 : \mu_T - \mu_S \leq L \text{ or } \mu_T - \mu_p \leq 0 \text{ or } \mu_S - \mu_p \leq 0 \\ \text{vs.} \\ H_a : \mu_T - \mu_S > L \text{ and } \mu_T - \mu_p > 0 \text{ and } \mu_S - \mu_p > 0 \end{aligned} \quad (9)$$

where μ_p is the average efficacy of the placebo.

In addition to hypothesis 3 for assessment of one-sided equivalence in efficacy between the test and the standard drugs, there are two more one-sided hypotheses for evaluation of the superiority in effectiveness of the test and the standard drugs as compared to the placebo:

Table 1 Criteria for Evaluation of Active Control Trials

1. Is the standard therapy effective, and does the experimental therapy have an advantage which is generalizable?
2. Can an acceptable minimum effect be defined in terms of the outcome measures?
3. Can this effect be measured precisely?
4. Was the assignment of patients to treatments really randomized?
5. Was the time frame for follow-up sufficient to conclude that the therapies are equivalent?
6. Were factors that which determined participation in the study identical to those for receiving the standard therapy?
7. Is it probable that the groups differ by less than a minimum effect?
8. Were all patients who entered the study accounted for at its conclusion?
9. Were the treatments administered as they would be in practice?

(From Kirshner [27]).

Table 2 Hamilton Depression Scale Endpoint Mean Score

Study	Baseline	Placebo	Test	Imipramine	<i>p</i> value ^a	Power ^b
R301	23.9	14.8 (<i>n</i> = 36)	13.4 (<i>n</i> = 33)	12.8 (<i>n</i> = 33)	0.78	0.40
G305	26.6	13.9 (<i>n</i> = 36)	13.0 (<i>n</i> = 39)	13.4 (<i>n</i> = 30)	0.86	0.45
C311	28.1	18.9 (<i>n</i> = 13)	19.4 (<i>n</i> = 11)	20.3 (<i>n</i> = 11)	0.81	0.18
V311	29.6	23.5 (<i>n</i> = 7)	7.3 ^c (<i>n</i> = 7)	9.5 ^c (<i>n</i> = 8)	0.63	0.09
F313	37.6	22.0 (<i>n</i> = 8)	21.9 (<i>n</i> = 7)	21.9 (<i>n</i> = 8)	1.00	0.26
K317	26.1	10.5 (<i>n</i> = 36)	11.2 (<i>n</i> = 37)	10.8 (<i>n</i> = 32)	0.85	0.33

^aTwo-tailed *p*-values for detection of a difference between the test drug and imipramine.

^bCalculated for a 30% difference between the test drug and the imipramine.

^cStatistically significant difference from placebo at *p* < 0.001, two-tailed. (From Leber [20]).

$$\begin{aligned} H_{0T} : \mu_T - \mu_p \leq 0 \text{ vs. } \mu_T - \mu_p > 0 \\ \text{and} \\ H_{0S} : \mu_S - \mu_p \leq 0 \text{ vs. } \mu_S - \mu_p > 0 \end{aligned} \tag{10}$$

The parameter space of the null hypothesis in Eq. (9) is the union of the spaces of the three null hypotheses in Eqs.(3) and (10). On the other hand, the parameter space of the alternative hypothesis is the intersection of the spaces of the three alternative hypotheses. Hence, if all three one-sided null hypotheses are rejected at the a significant level, then, by intersection-union principle,^[30] the null hypothesis in Eq. (9) is rejected at the α significance level, and it is concluded that the efficacy of both test and reference drugs are superior to the placebo and are equivalent. This procedure may be called the three one-sided test procedure. Although this procedure can control the consumer’s risk under the nominal level of significance, it is undoubtedly very conservative.

EQUIVALENCE LIMIT

For bioequivalence testing and some therapeutic areas, the equivalence limits are usually expressed in terms of the standard response.^[2,28] As a result, equivalence limits are unknown parameters that must be estimated. See the entry “Equivalence Trials” for discussion of this issue. On the other hand, for one-sided therapeutic equivalence, the lower limit *L* may be determined by previous experience about estimated relative efficacy with respect to the placebo and by the maximum allowance below which clinicians consider to be therapeutically acceptable.

With these considerations, it is quite awkward to have an equivalence limit for evaluation of no worse efficacy as large as or even larger than the treatment difference between the standard drug and the placebo. For example, in the treatment of perennial allergic rhinitis, the efficacy is assessed based on an average daily total symptom score over duration of treatment, which is the sum of four individual symptom scores, each with a range from 0–3. It seems reasonable to select an equivalence limit of 3.2 for

evaluation of therapeutic equivalence between a test product and the standard drug because 3.2 represents 25% of the range for the total symptom scores. However, this limit of 3.2 is considered unreasonably liberal as one realizes that improvement in each of the four individual symptom scores, provided by the standard drug over the placebo and estimated from adequate well-controlled studies with sufficient power, is only about 0.5.

Another example is provided in Continuous Infusion versus Double-bolus Administration of Alteplase (COBALT). For fibrinolytic therapy in treatment of suspected acute myocardial infarction, the 30-day mortality rate is around about 12% for the placebo group and is about 8% for tissue plasminogen activator (t-PA, or alteplase^[31]). As a result, the treatment effect of t-PA against placebo is estimated as 4%. To test the hypothesis that double-bolus alteplase is at least as effective as accelerated infusion of alteplase, the COBALT investigators employed an equivalence limit of 0.4%.^[32] This limit is 1/10 of estimated relative treatment effect against placebo. This implies that the upper limit of deaths allowed for the double-bolus alteplase, to be considered therapeutic equivalent to accelerated infusion, is 4 more deaths per 1,000 patients. This number is fewer than 5.6 per 1,000 patients between alteplase and streptokinase.^[32] The estimated difference in the 30-day mortality between double-bolus and accelerated infusion of alteplase is 0.44% with a 95% upper confidence limit of 1.49%. As a result, double-bolus alteplase is not therapeutically equivalent to accelerated infusion of alteplase with respect to an equivalence limit of 0.4%. Therefore, pre-specified equivalence limit for therapeutic equivalence evaluated in a non-inferiority trial should always be selected as a quantity smaller than the difference between the standard drug and the placebo that a superior trial is designed to detect. Even so, the selection of equivalence limit remains the most controversial issue in a non-inferiority trial. The reasons, as illustrated above, are twofold: (i) the ultimate and real goal of any non-inferiority trial is to prove that efficacy of the test treatment is better than that of the placebo although it is no worse than the active control, and (ii) the placebo group is not concurrently included

in non-inferiority trials. Historical information about the relative efficacy of the active control as compared to the placebo group must be utilized in the selection of equivalence limit. For more discussion of the determination of equivalence limit in non-inferiority trials, see Hung,^[33] Snapinn,^[34] Kallen and Larsson,^[35] Tsong et al.,^[36] and Wittes.^[37] For Bayesian approach to incorporating the historical active and the placebo effect in evaluating therapeutic equivalence, see Simon.^[38]

RECENT DEVELOPMENT

In the framework of hypothesis testing and regulatory considerations, Rothmann, et al.^[39] have addressed the design and analysis of non-inferiority trial based on survival for oncology trials. The European Committee for Medical Products for Human Use (CHMP) issued a guideline for selection of non-inferiority margin.^[40] In addition, Chan^[41] has reviewed exact non-inferiority tests based on binary data. Non-inferiority testing has been applied to evaluation of accuracy of diagnostic devices.^[42–46] Liu^[47] has demonstrated the application of non-inferiority to evaluation the safety hazard of drug products. For more discussion on therapeutic equivalence, see Rohmel,^[48] Ebbutt and Frith,^[49] Fleming,^[50] Ng,^[51] and two recently published special issue on non-inferiority trial in *Statistics in Medicine*.^[52,53]

CONCLUSION

For a non-inferiority trial, the objectives of evaluation for equivalence between the test and the standard drugs and for superiority of both drugs over the placebo should be clearly stated in the protocol. In addition, the equivalence limit should also be pre-specified in the protocol with clinical and statistical justification. Because the equivalence limit L is always smaller than the average difference between the active treatments and the placebo, the sample size per group determined by the formulas for equivalence will be large enough to provide sufficient power for verifying effectiveness of both test and standard drugs as formulated in hypotheses 10.

As indicated in ICH,^[10] an adequate active control in a non-inferiority trial should be a widely used standard, whose efficacy with respect to the placebo in the relevant indication has been clearly established and quantified in well-designed and well-documented superiority trial. Furthermore, the standard drug can be expected to exhibit a similar efficacy in the current planned ACET. As a result, the current ACET should have the same critical design features as the previously conducted superiority trials in which the standard has clearly demonstrated clinically relevant efficacy. These critical design features include primary

endpoints, the dose of the standard, inclusion and exclusion criteria, and so on. However, with respect to inference to the target population, there is a distinct difference between superiority trials and ACETs. For superiority trials, the patients randomly assigned to the standard should be comparable with those assigned to the placebo in terms of their risk of developing the outcome. On the other hand, for ACETs, one must assume that patients assigned to the test drugs are nearly identical in terms of how they would respond to the standard drug.^[27]

In general, the intention-to-treat (ITT) analysis will provide an estimate for the treatment effect of a smaller magnitude than the per-protocol (PP) analysis. As a result, for a superiority trial, ITT analysis is conservative in establishing the efficacy. On the other hand, others^[54] claim for a non-inferiority trial; an ITT analysis will not be conservative and is more likely to conclude therapeutic equivalence than a PP analysis. However, patients in an ITT analysis include protocol violators such as failure to satisfy the inclusion/exclusion criteria, poor compliance, loss to follow-up, and missing data. The PP analysis includes the patients who satisfy some criteria such as completion of a minimum pre-specified exposure to the treatment, availability of measurements of the primary endpoints, and absence of any major protocol violation. Therefore, the patients in an ITT analysis are more heterogeneous than those included in a PP analysis. Therefore, the ITT analysis will use a larger variability in evaluation of equivalence than the PP analysis. Hence, the ITT analysis is not necessarily more likely to conclude therapeutic equivalence.

Thorough QT Studies

Joanne Zhang, Dalong (Patrick) Huang, and Yi Tsong

Office of Biostatistics, Office of Translational Sciences, CDER, U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.

Abstract

After the International Council for Harmonization (ICH) E14 guidance was released in 2005, the thorough QT (TQT) clinical study has been required in early drug development for most compounds. The purpose of the guidance is to provide recommendations to sponsors concerning the design, conduct, analysis, and interpretation of TQT studies. The objective of the study is to exclude a clinically significant increase of drug-induced QTc (QT intervals corrected by the heart rate) intervals. However, the guidance is not clear or specific on a lot of practical details. In this entry, we will address issues including study design, sample size, statistical analysis, assay sensitivity, QT correction methods, how to prespecify time points, and how to collect baseline values for a TQT study. Other than the traditional crossover and parallel studies, a special “nested” crossover design within a parallel study will also be discussed. In addition, using concentration-QTc (C-QTc) modeling to study the relationship between Δ QTc (change from baseline) and $\Delta\Delta$ QTc (placebo adjusted change from baseline) and plasma concentration is also discussed. Suggestions of how to use C-QTc relationship analysis to avoid TQT studies are also provided. The ICH E14 Question and Answer (Q&A) document (2014) emphasized the value of C-QTc modeling, and it enables pharmaceutical companies to use C-QTc modeling as the primary analysis for assessing QTc prolongation risk of new drugs. A new approach by including the time factor into the current C-QTc model is also introduced. Cautions of using C-QTc method in early phase are discussed as well.

Keywords: Thorough QT studies; QT study design; QT correction methods; TQT analysis; Assay sensitivity; Concentration-QTc modeling.

INTRODUCTION

The QT interval is measured from the beginning of Q wave to the end of T wave on an ECG tracing (Fig. 1). It reflects the duration of ventricular depolarization and subsequent repolarization of ventricular myocytes. For some drugs, significant prolongation of the QT interval has been associated with precipitating a potentially fatal cardiac arrhythmia called Torsades de Pointes (TdP), which can degenerate into ventricular fibrillation, leading to sudden cardiac death.^[1,2] Due to the risk of TdP, several drugs have been withdrawn from US market.^[3]

In 2005, the International Council for Harmonization (ICH) issued the E14 guidance, “The Clinical Evaluation of QT/QTc Interval Prolongation and Proarrhythmic Potential for Nonantiarrhythmic Drugs.” After this guidance was released, regulatory agencies requested that each pharmaceutical company conduct one TQT study when submitting an application for most new nonantiarrhythmic drugs, except for large therapeutic proteins and products that do not enter the bloodstream in any meaningful amount. The purpose of the guidance is to provide recommendations to sponsors concerning the design, conduct, analysis, and interpretation of TQT studies. The guidance suggests that

the TQT study be conducted in early clinical development when some information about the pharmacokinetics of the drug has been obtained.

According to ICH E14 guidance,^[4] a typical TQT study should be a randomized, double blinded, placebo- and active-controlled, crossover, or parallel-arm study conducted with healthy subjects. All subjects are administered either a single dose or multiple doses of the study drug. The objective of a TQT study is to demonstrate the lack of a QTc effect; here QTc is the heart rate corrected QT interval, which is used to remove the effect of heart rate.

If the data collected provide enough evidence to show that the drug does not prolong the QTc interval in a clinically significant manner when compared with placebo, the TQT study is claimed to be a “negative study.” The guidance also recommends using a concurrent positive control arm to establish assay sensitivity. An appropriate positive control will increase the confidence to distinguish a small difference between placebo and the investigational drug.

The ICH E14 analysis is a conservative safety tool and a TQT study is not inexpensive. In 2012, the FDA QT-Interdisciplinary Review Team (QT-IRT) presented the idea of potentially avoiding a TQT study in a public forum.^[5] The presentation reported the coherence result between the

Fig. 1 ECG Waves. The P wave represents depolarization occurring within the atria of the heart. The QRS complex represents depolarization occurring within the ventricles of the heart. The T wave represents repolarization occurring within the ventricles of the heart. The QT wave is the period of time it takes to complete both depolarization and repolarization within the ventricles and is measured from the beginning of the Q wave to the end of the T wave

relationship of QTc to drug concentration (this relationship is measured through the slope) and ICH E14 findings (positive or negative TQT studies) based on hundreds of QT studies submitted to the FDA. The conclusion was that if the slope was not positive, in most cases (86%) the corresponding QT studies were also negative. If the slope was positive, 92% of the corresponding QT studies were also positive. The FDA QT-IRT proposed that by studying the relationship between concentration and QTc, one might use early phase I concentration and QTc data to eliminate the need for TQT studies. This presentation was later published in 2015.^[6] After this presentation, more research results have been published.^[7,8] The ICH E14 Question and Answer (Q & A) document was revised in December 2015. This document allows concentration-QTc (C-QTc) modeling to be the primary method for assessing the QTc interval. However, it is not clear whether a TQT study is still needed. The authors believe that for some compounds, C-QTc modeling might still have its limitations and a TQT type of study might still play an important role.

In this entry, the statistical approaches and issues in the design and analysis of a TQT study as well as C-QTc modeling will be discussed. The terms of negative study and negative compound are interchangeable (meaning that the QT liability of the new drug can be excluded), as with positive study and positive compound (meaning that the QT liability of the new drug cannot be excluded).

QT INTERVAL CORRECTED BY ITS HEART RATE

The ECG records the electrical activities of a human heart. Figure 1 displays an ECG of two heartbeats. The QRS

complex represents depolarization occurring within the ventricles of the heart. The T wave represents repolarization occurring within the ventricles of the heart. The period from the beginning of the Q wave to the end of the T wave defines the QT interval and represents the total time required for both ventricular depolarization and repolarization. The time between two consecutive R waves, the RR interval, is inversely proportional to the heart rate, or QT interval increases with RR interval. In order to eliminate unwanted heart rate effects, the QT interval is generally corrected for heart rate, denoted as the QTc interval.

Commonly used correction formulas include fixed correction methods, population correction methods, and individual correction methods.

A fixed correction method uses a fixed correction formula that is not derived from the current trial data. The most commonly used fixed correction methods are Bazett's^[9] and Fridericia's^[10] formulae (1920). Based on his empirical experience, Bazett assumed the relationship $QT = \alpha \times RR^{1/2}$, which yields $QTc = QT/RR^{1/2}$. Fridericia's formula is $QTc = QT/RR^{1/3}$. This formula is often considered an improvement over Bazett's correction, because it improves the QTc consistency among different subjects.

In addition, Schlamowitz^[11] proposed to use $QTc = QT/RR^{0.205}$ for correction and the Framingham^[12] study (1992) used $QTc = QT/RR^{0.154}$. The fixed correction methods do not account for the variation in the QT versus RR relationship from population to population. This led to the population-based correction method.

A population-based correction method assumes that subjects under the same treatment (on or off drug) share the same but unknown correction factors which need to be estimated through the data. This method usually fits a regression model to the pooled drug-free QT-RR data from all subjects in the current trial.

However, some researchers pointed out the variation in the QT versus RR relationship from subject to subject.^[13–15] They presented evidence that each individual has a different profile of QT against RR. This has led to individual correction methods, an idea first introduced by Dr. Marek Malik.^[13,16] This method often fits a regression model to QT-RR data from each individual's QT and RR measurements at baseline.

Different correction methods have been compared under different models in numerous studies using clinical data.^[1,13,17–20] The goal of a good correction method is to remove the dependency of QTc on RR intervals within subjects. The conclusions of the comparisons were dependent on subject composition and the observed range of RR intervals. Most of the comparisons were focused on the model error which is the intra-subject mean difference. With these constraints, the "error" term would be partially attributed to the data grouping and the outcome of the "error" term may not entirely correspond to the actual biases of the correction methods.

For drugs without a substantial effect on the heart rate, the difference among different correction methods might be small. Based on our experience, Fridericia's correction method works well for a well-conducted QT study. However, if the study drug changes heart rate or has other autonomic effects, the individual correction method with a wide range of RR intervals might work better.^[21] Like any data-driven correction method, the individual correction method will introduce uncertainty for the correction factors. The variability of correction factors is usually ignored and the issue needs further investigation.

There is a concern about the discrepancy of the results by using different correction methods. If this occurs, careful evaluation of the data quality is needed.

ASSESSMENT OF TREATMENT-INDUCED PROLONGATION OF QTc INTERVAL

The ICH E14 guidance^[4] sets the threshold level of regulatory concern for the test drug at a mean effect on QTc of around 5 ms but requires as evidence that a one-sided 95% (or two-sided 90%) upper confidence bound for the largest baseline adjusted mean difference between the study drug and placebo be less than 10 ms. This actually does not make any statistical sense. An upper bound less than 10 ms only indicates that the mean effect is no greater than 10 ms. In practice, instead of testing 5 ms, the mean difference of 10 ms between the study drug and placebo has been tested. The non-inferiority margin of 10 ms was chosen based on clinical experience of the ICH E14 committee. The authors of this entry think the margin may be changed when more experience has been gained.

Let $\mu_T(j)$ and $\mu_P(j)$ denote the mean QTc (or baseline-adjusted QTc) interval of subjects receiving test and placebo treatment, respectively, at time point j , and let $\delta_{TP}(j) = \mu_T(j) - \mu_P(j)$, $j = 1$ to J , where J is the total number of time points. Then, the following statistical hypotheses can be considered for the ICH E14 analysis:

$$H_0 : \text{Max}_{j=1 \text{ to } J} [\delta_{TP}(j)] \geq 10 \text{ ms}$$

versus

$$H_a : \text{Max}_{j=1 \text{ to } J} [\delta_{TP}(j)] < 10 \text{ ms} \quad (1)$$

In practice, it is represented by testing the following null hypotheses by time points:

$$\begin{aligned} H_0(j) : \delta_{TP}(j) &\geq 10 \text{ ms} \text{ versus} \\ H_a(j) : \delta_{TP}(j) &< 10 \text{ ms at all } j = 1 \text{ to } J \end{aligned} \quad (2)$$

The trial is concluded negative when all J null hypotheses in (Eq. 2) are rejected. TQT trials are usually carried out in a single clinical center with healthy subjects. The null hypotheses are rejected by showing that

$$T_j = \frac{\hat{\delta}_{TP}(j) - 10}{e(\hat{\delta}_{TP}(j))} < t(n^*; 0.05)$$

at each time point, where $\hat{\delta}_{TP}(j)$ is the unbiased estimate of $\delta_{TP}(j)$, $e(\hat{\delta}_{TP}(j))$ is the standard error of $\hat{\delta}_{TP}(j)$, and $t(n^*, 0.05)$ is the fifth percentile of the t distribution with n^* degrees of freedom (determined by the sample sizes of the test and placebo groups as well as the design model).

Equivalently, one may reject each of the null hypotheses of (Eq. 2) by showing that one-sided 95% upper confidence interval of $\delta_{TP}(j)$ is less than 10 ms at each time point,

$$U = \hat{\delta}_{TP}(j) + t(n^*; 0.95)e(\hat{\delta}_{TP}(j)) < 10 \text{ ms}, j = 1 \text{ to } J$$

It has been shown that this intersection-union test is very conservative and the type I error rate α is well controlled.^[22] Furthermore, this approach was shown by Berger^[23] to be uniformly most powerful among all monotone, α -level tests for the linear hypotheses (Eq. 2). However, when J is large, this approach usually has low power.

Boos et al.^[24] showed that $\text{Max}_{j=1 \text{ to } J} \hat{\delta}_{TP}(j)$ is a biased estimate of $\text{Max}_{j=1 \text{ to } J} \delta_{TP}(j)$ and $E[\text{Max}_{j=1 \text{ to } J} \hat{\delta}_{TP}(j)] \geq \text{Max}_{j=1 \text{ to } J} \delta_{TP}(j)$. An appropriate bias correction method has not been developed yet.

Cheng et al.^[25] proposed an asymptotic test based on distribution of the maximum of correlated random variable to study drug induced QTc prolongation. At present, there is not much experience with this method.

VALIDATION TEST

For the purpose of clinical trial validation (i.e., assay sensitivity), a positive control arm is usually considered in a TQT study. Such a validation process will enhance confidence in the ability of the study to detect a small change in QTc intervals, especially when the outcome of the trial is negative. ICH E14 guidance^[4] states that “the positive control should have an effect on the mean QT/QTc interval of about 5 ms (i.e., an effect that is close to the QT/QTc effect that represents the threshold of regulatory concern, around 5 ms). This statement can be formed as a statistical hypothesis.^[26]

Let $\mu_C(j)$ and $\mu_P(j)$ denote the mean QTc interval at the j -th time point after the baseline adjustment for the positive control and placebo, respectively. Let $\delta_{CP}(j) = \mu_C(j) - \mu_P(j)$. The hypotheses of interest for assay sensitivity are

$$H_0 : \text{Max}_{j=1 \text{ to } J} \delta_{CP}(j) \leq 5 \text{ ms}$$

versus

$$H_a : \text{Max}_{j=1 \text{ to } J} \delta_{CP}(j) > 5 \text{ ms} \quad (3)$$

Similar to the non-inferiority test of treatment-induced QTc prolongation, the conventional approach is to test the J sets of hypotheses,

$$\begin{aligned} H_0(j) : \delta_{CP}(j) &\leq 5 \text{ ms against} \\ H_a(j) : \delta_{CP}(j) &> 5 \text{ ms for } j = 1 \text{ to } J \end{aligned} \quad (4)$$

the null hypothesis can be rejected as long as the lower limit of at least one confidence interval of $\delta_{CP}(j)$ is greater than 5 ms, i.e.

$$L = \hat{\delta}_{CP}(j) + t(n^*; \alpha^*)e(\hat{\delta}_{CP}(j)) > 5 \text{ ms} \quad (5)$$

for at least one j , $j = 1$ to J with a properly adjusted type I error rate α^* .

As the statistic introduced in Section II, $\text{Max}_{j=1 \text{ to } J} \hat{\delta}_{CP}(j)$ is also a biased estimate of $\text{Max}_{j=1 \text{ to } J} \delta_{CP}(j)$. Unlike testing (Eq. 1) or (Eq. 2), testing (Eq. 3) or (Eq. 4), using $\alpha = 0.05$ for each individual test would inflate family type I error rate because of multiple comparisons. A simple conservative approach would be using the Bonferroni adjustment with $\alpha^* = 0.05/J$ for each individual test in the conventional intersection-union test or estimating each individual confidence interval in (Eq. 5). Power of the validation test can be improved using many Bonferroni-modified (stepwise) procedures. For example, let $p_{(1)} \geq p_{(2)} \geq \dots \geq p_{(J)}$ be the ordered p -values of the J tests, and $H_{0(1)}, H_{0(2)}, \dots, H_{0(J)}$ be the corresponding ordered null hypotheses. Using Holm's procedure (1979),^[27] the study is validated if $p_{(J)}$, the smallest p -value is less than $0.05/J$. Validation fails if $p_{(J)} \geq 0.05$. On the other hand, using Hochberg's procedure (1988),^[28] the study is validated if $p_{(j)} < 0.05/j$ for any $j = 1, \dots, J$. Furthermore, if the covariance structures of the measurements across all the time points are known, the power can further be improved by using Holm's procedure.^[29]

In practice, it is not efficient to perform statistical tests over the entire time course if the peaking time of the positive control arm can be anticipated based on the pharmacokinetic (PK) information. For instance, if we know that the observed maximum QTc effect of the positive control occurs around times $t_1, t_2, \dots, t_K$, then it is sufficient to focus our statistical test just on those K points, where $K < T$.

With a clear signal of QT prolongation and well-behaved PK profile, moxifloxacin, a fluoroquinolone antibiotic, is usually considered for a positive control in a TQT study.^[30] Its maximum QTc effect is around 10 ms or larger and usually occurs between hour 1 and 4 hours after a single dose of 400 mg tablet of administration; therefore, it might be sufficient to evaluate the QTc effect of moxifloxacin only between hours 1 and 4.^[26] Therefore, the multiple comparison adjustment can be performed only on 3 or 4 time points.

Alternatively, in order to test if moxifloxacin has a 5 ms effect, we can look at the average baseline adjusted mean differences of the positive control and placebo around $T_{\max}$.

The parameter of interest is $m_M - \mu_P = \frac{1}{K} \sum_{i=1}^K (\mu_M(i) - \mu_P(i))$,

where $\mu_M(i)$ and $\mu_P(i)$ are the baseline adjusted mean QTc interval at the i -th time point for moxifloxacin and placebo, respectively, and K is usually 3 or 4. If the statistical hypotheses is set up based on this parameter $m_M - \mu_P$, then there is no need to adjust for multiple time points.^[26]

To complete the validation test, usually the QTc profile of the baseline adjusted mean difference between moxifloxacin and placebo over the entire time course should be consistent with the expected QTc moxifloxacin time course profile. A typical moxifloxacin profile is displayed in Fig. 2 with a rising phase, the peaking time, and a declining phase.

Fig. 2 General time course of Moxifloxacin effect of a double-blind randomized study (Mean baseline adjusted Moxifloxacin – placebo difference and its 90% confidence interval)

SAMPLE SIZE AND DESIGN ISSUES OF TQT STUDIES

Like any clinical trial, the sample size of a TQT study can be calculated based on the hypotheses, statistical models, the desired power for a chosen alternative hypothesis and the variability of the study.^[22,31,32] For different study designs, the sample size required for the study will be different. For a typical crossover TQT study, approximately 45 subjects is a reasonable estimate for any number of treatment arms. For a parallel study though, each arm should have about 45 subjects. Therefore, a parallel study needs a much larger sample size, especially when treatment arms are large.

A TQT study is a randomized, double-blinded, placebo- and positive-controlled, crossover or parallel study with single or multiple doses of the study drug. TQT studies are usually conducted in populations of healthy subjects. However, there are some drugs or the high doses of certain drugs that healthy volunteers cannot tolerate due to safety concerns. In such cases, a TQT study can be conducted in patient populations.

The ICH E14 guidance^[4] suggests that a crossover TQT study is preferable since it needs significantly fewer subjects than a parallel study. In addition, since the same subject acts as her/his own control, the precision of the estimated treatment differences is greater than that for a parallel design with the same number of subjects. One of the major concerns for a crossover study is the potential carryover effect. Hence, it is important to have a sufficient washout period between any two treatments.

For a crossover design, a sequence is a prespecified ordering of the treatments to the periods. The randomization of the clinical trial is achieved by randomly assigning the subjects to one of the sequences for the treatments. For example, the following sequences may be considered for a three-arm trial:

Latin Square 1: Sequence #1: T/P/C;
Sequence #2: C/T/P;
Sequence #3: P/C/T;
Latin Square 2: Sequence #4: T/C/P;
Sequence #5: C/P/T;
Sequence #6: P/T/C;

Here, T, C, and P are the test, positive control, and placebo treatments, respectively.

A sequence-balanced complete crossover trial design for more than two treatments is often represented by a group of Latin squares. The first three sequences and the second three sequences given above form two different Latin squares. For a study with 48 subjects, a complete balanced crossover design is to have eight subjects randomly assigned to each of the six sequences above. The most frequently used crossover design in a TQT trial is the Williams square design.^[33] A Williams square is a specific Latin square with two treatments appearing in two

consecutive periods and in reversed order exactly once. This design is balanced for the first order carryover effects. The Williams square is a variance-balanced design, which means that the variance between any two estimated direct treatment effects is the same. A variance-balanced design has the property that each treatment will be equally precisely compared with every other treatment.^[34] The direct-by-carryover interaction is significant if the carryover effect of a treatment depends on the treatment applied in the immediately subsequent period. If the study model includes period, sequence, treatment, first-order carryover, and direct-by-carryover interaction as fixed effects, the design based on one or two Williams squares might not have sufficient degrees of freedom to assess direct-by-carryover interaction. If this is the case, one might consider using a design with repeated multiple Latin squares, or complete orthogonal sets of Latin squares. For the three treatments, with 48 subjects, the Williams design is also a completely orthogonal set of Latin squares.^[34,35]

For a trial with an even number of treatment arms, usually one Williams square can achieve the goal of balancing all treatment arms. For a TQT study, if one Williams square is implemented, it is better to conduct a double-blinded trial because if the code of which Williams square being used is broken, the whole study may become open-labeled. The FDA does not require double-blinding the positive control arm, moxifloxacin, in TQT studies; however, both the study drug and placebo arms still need to be double-blinded. In a clinical trial, when one arm is open-labeled, it creates more opportunities to break the blinding code for other treatment arms. Fortunately, it is not difficult to overcome this problem. If moxifloxacin is open-labeled, one can apply at least two Williams squares as shown below.

Williams square 1

	Period 1	Period 2	Period 3	Period 4
Sequence 1	B	C	A	MOXI
Sequence 2	C	MOXI	B	A
Sequence 3	A	B	MOXI	C
Sequence 4	MOXI	A	C	B

Williams square 2

	A	B	C	MOXI
Sequence 1	A	B	C	MOXI
Sequence 2	B	MOXI	A	C
Sequence 3	C	A	MOXI	B
Sequence 4	MOXI	C	B	A

Williams square 3

	C	A	B	MOXI
Sequence 1	C	A	B	MOXI
Sequence 2	A	MOXI	C	B
Sequence 3	B	C	MOXI	A
Sequence 4	MOXI	B	A	C

Here A, B, C denote the two doses of the study drug and placebo arm, respectively. MOXI is for moxifloxacin. Even though patients or investigators know which two Williams squares have been used in a TQT study with an open-labeled moxifloxacin administration, they do not know exactly which other treatments they are receiving. For instance, if moxifloxacin was administered in Period 1, subjects may receive either treatment A or treatment C in period 2, even though they know that they will not receive treatment B. If a third Williams square is added, after moxifloxacin is given, there is an equal opportunity for each other treatment being given after moxifloxacin.

The potential danger one needs to consider is that the sample size might be too small to allow for enough degrees of freedom.

A parallel group design may have to be used when the study drug has a long elimination half-life or long-lived active metabolites for which a long time interval would be required to achieve steady-state, or when the study drug has a large number of dose groups to be evaluated. In a situation where the anticipated dropout rate is high, a parallel design is worth consideration as well since the duration of a parallel study is shorter than a crossover study. The biggest disadvantage of a parallel design is the large number of subjects required. To reduce the sample size, researchers proposed a “nested-crossover” alternative design,^[36,37] in which a combined placebo/positive control group can be considered. If moxifloxacin is used for the positive control, a 2×2 crossover between moxifloxacin and placebo can be “nested” within the parallel study. For demonstration purpose, assume that we have three treatment arms. The study drug needs multiple days (m days) of exposure and a parallel comparison with the placebo is determined for the study drug. By using the conventional three-arm parallel design, approximately 135 subjects are needed (about 45 subjects in each treatment arm). Alternatively, one can consider the following design (Table 1). Forty-five subjects can be assigned to Group 1 (the study drug). Twenty-three subjects can be assigned to Group 2 and Group 3, respectively. By considering this design, only 91 subjects are needed.

Even though the sample size is reduced, the price to pay is to collect more ECG data. In addition to Day 0 and Day m , ECGs at Days 1 and $m + 1$ are also required for the statistical analysis.

The ICH E14 guidance^[4] suggests that the concentration-response relationship for QTc prolongation be

characterized. To achieve this, the duration of dosing or a dosing regimen, along with the timing of the collection of ECGs, should be sufficient to capture the PK and PD properties of the drug and its metabolites. Zhang and Stockbridge^[38] described how to prespecify the time points for a TQT study. In a TQT study, a time-matched ECG between each treatment group including the positive control arm and placebo should be collected. It is recommended^[39] the replicate ECGs at each time point be considered. Usually three to five replicates at each pre-specified time point should be obtained within a 2–5 minute period. It is shown that a triplicate ECG at each time point might be sufficient.^[39]

Due to large inter-subject variability, a time-matched baseline adjustment is usually recommended to correct for diurnal variability. The baseline ECG should be collected at least at those time points where post-dose ECG is measured. However, for a crossover design, if the study drug does not change the heart rate, a time-matched baseline might not be necessary. This is because in a crossover study, the diurnal variability of the QTc is accounted for by the design itself since each subject receives each of the treatments in the post-dose periods at exactly the same time points. For a parallel study though, whole day time-matched baseline measurements are needed in order to adjust for within-subject diurnal variability.^[40] When a wide range of RR intervals are needed, in addition to those time points pre-specified for the treatment groups, more time points at baseline might help for a better QT correction.

LESSONS LEARNED FROM HUNDREDS OF THOROUGH QT STUDIES

Since the release of the ICH E14 guidance^[4] and beginning the use of TQT studies as part of the drug approval process, no drugs have been withdrawn from the market due to TdP risk. However, based on many years of experience, it has been realized that the TQT study and the ICH E14 standard are overly conservative. If a TQT study can be replaced by something less complicated, if not for every new drug, but at least for most new applications, that will benefit the community. This was the motivation behind the 2012 comprehensive review of all the existing QT studies submitted to the FDA QT-IRT.^[5] The focus of this post hoc analysis was to examine the relationship between Δ QTc (change from baseline) or $\Delta\Delta$ QTc (placebo adjusted change from baseline) and plasma concentration. If this relationship could not be detected, in most cases, the corresponding QT studies were also negative. Based on the submissions, most of the QT studies are negative. If those negative studies can be identified without a TQT study, it will be more cost effective without compromising safety.

By the end of the year 2012, FDA had reviewed 277 unique QT studies from submissions by pharmaceutical

Table 1 Alternative design for a conventional parallel study

	Day 1 to Day m	Day $m + 1$
Group 1:	study drug	Placebo
Group 2:	Day 1: moxifloxacin	Placebo
	Day 2 to Day m : placebo	
Group 3:	Day 1 to Day m : placebo	Moxifloxacin

sponsors to the FDA, including 229 TQT studies and 48 non-TQT studies conducted among patients without a positive or a negative control arm. Among 277 TQT and non-TQT studies, 53 studies were missing pharmacokinetics (PK) information and one study had an obvious hysteresis between PK and QT. After excluding those 54 studies, 223 QT studies were analyzed, including 141 TQT crossover, 63 TQT parallel, and 19 non-TQT studies.

For each of the 223 selected QT studies, a basic mixed model of ΔQ_{Tc} or $\Delta\Delta Q_{Tc}$ versus concentration or log of concentration was considered:

$$Y_{ij} = \alpha_i + \beta_i X_{ij} + \epsilon_{ij}, \quad i = 1, 2, \dots, n$$

where $Y_{ij} = \Delta Q_{Tc}$ or $\Delta\Delta Q_{Tc}$ for the i th subject at the time point j ; n is the number of subjects; X_{ij} = concentration or log(concentration) for the i th subject at the j th time point; and β_i is the slope for the i th subject, which is a random variable with the expectation $E(\beta_i) = \beta$. Here, β is the population fixed effect, a parameter of interest. The statistical hypotheses considered were as follows:

$$H_0 : \beta \leq 0 \text{ vs. } H_a : \beta > 0 \tag{6}$$

ΔQ_{Tc} was used for parallel or single-arm studies and $\Delta\Delta Q_{Tc}$ was applied for crossover studies. If there was no significant effect or a negative concentration effect on ΔQ_{Tc} or $\Delta\Delta Q_{Tc}$, no relationship between the ΔQ_{Tc} , or $\Delta\Delta Q_{Tc}$ and the plasma concentration would be concluded.

The baseline values for most parallel studies were collected the day prior to the dosing day, which was a time-matched whole-day baseline. For most crossover studies, the baseline values were based on a few pre-dose time points on the day of dosing. After concentration-QTc relationship (C-QTc relationship) analysis, the results were compared with the findings (positive or negative QT studies) based on the ICH E14 analysis. The two approaches were considered to be coherent if (a) H_0 could not be rejected in Equation (V.1) and H_0 in Eqs. 1 or 2 was rejected or (b) H_0 in Eq. 5 was rejected and H_0 in Eqs. 1 or 2 could not be rejected. The results for the sensitivity and specificity of C-QTc relationship analysis were also reported. Sensitivity was defined to be the proportion of negative studies based on the ICH E14 approach that were correctly identified as having no relationship through hypotheses in Eq. 7. Specificity was defined to be the proportion of positive studies based on ICH E14 analysis that were correctly identified as having a relationship by rejecting H_0 in Eq. 7.

The overall coherence rate was about 87%. The overall sensitivity and specificity were about 86% and 92%, respectively. One can find more detailed results in Zhang et al., 2014. Based on the high sensitivity and specificity, Zhang^[6] recommended studying the relationship between ΔQ_{Tc} or $\Delta\Delta Q_{Tc}$ and the drug plasma concentration when proper single ascending dose (SAD) and multiple ascending dose (MAD) studies are available. If the relationship

could not be detected based on hypotheses in Eq. 6, and the two-sided 90% upper confidence interval at a fixed concentration level (50th or 75th percentile, or mean peak plasma concentration C_{max}) was below a certain threshold level (e.g., 10 ms), then a TQT study might be unnecessary. The reason to calculate a 90% confidence interval is to avoid making a wrong decision when there is no relationship, but the ΔQ_{Tc} or $\Delta\Delta Q_{Tc}$ effect is still high due to either a narrow dose range or missing the rising phase of the PK profile. Theoretically, it does not matter at what concentration level ΔQ_{Tc} or $\Delta\Delta Q_{Tc}$ is evaluated at if the slope is flat. There is no statistical test involved in this evaluation. If the relationship can be established and the 90% lower confidence bound at a fixed concentration level (e.g., mean C_{max}) is greater than 10 ms, further investigation is needed. If the signal is real, one might choose intensive safety monitoring during later drug development for a potentially effective compound. However, there are some gray areas in which this analysis alone cannot determine the potential QT liability of the drug, and a TQT type of study is still worth considering.

A NEW APPROACH TO C-QTC MODELING

Huang et al.^[41] discussed some statistical issues of the traditional C-QTc modeling and introduced a modified C-QTc method including the mean circadian rhythm effect into the model. Based on the characteristics of the study setting, they simulated a SAD type of study (the schema of the study is shown in Table 2). A total of nine different doses (ranging from 5 mg to 800 mg) were considered with three cohorts. Each cohort is a 3 × 3 crossover design with two different doses plus placebo in three periods for each sequence. Twelve subjects were equally distributed among three sequences per cohort. The drug concentrations and ECGs were measured at the baseline, 0.5, 1, 2, 3, 4, 8, 12, 24 hr after the first administration of the drug/placebo.

Table 2 Phase 1 crossover single ascending dose study design schema

Cohort	Number of			
	subjects	Period 1	Period 2	Period 3
1	N = 4	5 mg	50 mg	Placebo
	N = 4	5 mg	Placebo	400 mg
	N = 4	Placebo	50 mg	400 mg
2	N = 4	20 mg	200 mg	Placebo
	N = 4	20 mg	Placebo	600 mg
	N = 4	Placebo	200mg	600 mg
3	N = 4	10 mg	100 mg	Placebo
	N = 4	10 mg	Placebo	800 mg
	N = 4	Placebo	100 mg	800 mg

In the simulation study, the QTc circadian rhythm was introduced using the same multioscillator function^[42] for all the subjects. The QTc interval was assumed to be linearly dependent on the drug concentration. The QTc values among different subjects were accomplished through the subject random effect. The QTc intervals within the same subject but at different periods were generated through the subject-by-period random effect. The random sampling error and the two random effects were assumed to be independent of each other. The modified C-QTc model was set up as follows:

$$QTc_{kjs} = QTc_0 + \text{Effect}(t_s) + \beta * C_{kjs} + b_k + b_{k(j)} + e_{kjs} \quad (7)$$

where QTc_{kjs} is the QTc measurement for the subject k in the j th period at time point t_s and QTc_0 is the grand mean QTc value at the baseline and set to be 410 ms. The mean circadian rhythm effect at time t_s , $\text{Effect}(t_s) = QTc_0(-0.03*\cos(2\pi(t_s-6)/24)-0.016*\cos(2\pi t_s/12))$. C_{kjs} is the observed drug concentration for the subject k in the j th period at time t_s . β is the slope which measures the relationship between QTc prolongation and the drug concentration. b_k , $b_{k(j)}$, and e_{kjs} denote the subject random effect, subject by period random effect and the random error, respectively. Suppose $b_k \sim N(0, \sigma_s^2)$ and $b_{k(j)} \sim N(0, \sigma_p^2)$ for the subject k at the j th period. The random errors have autoregressive order one (AR(1)) covariance structure with variance and correlation σ_e^2 and ρ , respectively. The reason AR(1) instead of the commonly used double-compound symmetry structure was chosen is that the correlation between the two QTc measurements may reduce as the time points are apart.^[43,44] With the total variance fixed at 300, eight scenarios of (σ_s^2 , σ_p^2 , σ_e^2) and 10 different correlations were considered (Table 3).

Each period had one predose and eight postdose QTc measurements at 0, 0.5, 1, 2, 3, 4, 8, 10, and 24 hours. The mean QTc value within each period was generated using the above mentioned function $\text{Effect}(t_s)$. The drug effect slope β was set to be $\Delta\Delta QTc/C_{\max}$. True $\Delta\Delta QTc = 10\text{ms}$ was considered.

Further, the following one-compartmental model^[45] was used to simulate the drug concentration,

$$C_{kjs} = \frac{\text{Dose} * K_{ak}}{V_k * (K_{ak} - K_{ek})} * (\exp(-K_{ek} * t_s) - \exp(-K_{ak} * t_s))$$

Table 3 Simulation scenarios and values of covariance parameters

Scenario	σ_s^2	σ_p^2	σ_e^2	ρ
1	225	30	45	0, 0.1, 0.2, ..., 0.8, 0.9
2	195	60	45	
3	180	45	75	
4	180	75	45	
5	165	90	45	
6	120	90	90	
7	90	120	90	
8	210	45	45	

where $K_{ak} = Ka * \exp(\eta_1)$, $Ka = 0.8 \text{ hr}^{-1}$, the absorption rate, $K_{ek} = CL_k/V_k$, $CL_k = CL * \exp(\eta_2)$,

$CL = 12,000 \text{ mL}$, the mean clearance, $V_k = V * \exp(\eta_3)$, $V = 40,000 \text{ mL}$ volume of distribution. Here, η_1 , η_2 , and η_3 are between-subject variability of all the population pharmacokinetics parameters, and they are assumed to be distributed as $N(0, 0.1^2)$. For demonstration purposes, the 600 mg dose was used to evaluate the QTc prolonging effect. The mean $C_{\max}$ of the 600 mg dose from the one-compartmental PK model was $8.327 \mu\text{g/mL}$. Each simulation was replicated 2000 times.

The most widely used C-QTc modeling is the linear mixed model (LMM) with a random slope and/or random intercept using concentration as the covariate. In this simulation, models with and without time were examined. Models without time effect were indicated as base LMM. Models by adding time effect alone and by adding time effect together with other covariates, such as baseline or treatment or both to the base LMM, were referred to as covariate LMM. Both ΔQTc and $\Delta\Delta QTc$ were evaluated. Both compound symmetry (CS) and unstructured (UN) variance-covariance were inspected (Table 4).

Through the simulation, they evaluated the false negative rate (FNR) (percentage of the upper bounds of 90% CIs that were below 10 ms when the true $\Delta\Delta QTc = 10 \text{ ms}$), the coverage probability (CP) (percentage of the 90% CIs that contained the true $\Delta\Delta QTc = 10\text{ms}$), and the relative bias (percentage bias between predicted $\Delta\Delta QTc$ and true $\Delta\Delta QTc$).

Table 4 Concentration-QTc analysis models in the simulation study

Model type	Model formulation	Covariance matrix structure
Base models (Base LMM)	$\Delta QTc_{kjs} = \alpha + \alpha_k + \beta * C_{kjs} + \beta_k * C_{kjs} + e_{kjs}$ $\Delta\Delta QTc_{kjs} = \alpha + \alpha_k + \beta * C_{kjs} + \beta_k * C_{kjs} + e_{kjs}$	CS, UN (α_k and β_k are random intercept and slope respectively)
Covariate Models (Covariate LMM)	$\Delta QTc_{kjs} = \alpha + \alpha_k + \beta * C_{kjs} + \beta_k * C_{kjs} + (\lambda_1 * T_s) + (\lambda_2 * \text{Baseline}_j) + (\lambda_3 * \text{Trt}) + e_{kjs}$ $\Delta\Delta QTc_{kjs} = \alpha + \alpha_k + \beta * C_{kjs} + \beta_k * C_{kjs} + (\lambda_1 * T_s) + (\lambda_2 * \text{Baseline}_j) + (\lambda_3 * \text{Trt}) + e_{kjs}$	CS, UN (α_k and β_k are random intercept and slope respectively)

The results of the simulation study were presented for the scenario ($\sigma_s^2=225$, $\sigma_p^2=30$, $\sigma_e^2=45$, and $\rho=0.3$), which is close to the variances and correlation observed in real TQT studies. The results for other scenarios in the simulations had a similar trend.

The performance of FNR with different models at three different sample sizes ($n=12, 24$, and 36) is displayed in Fig. 3. As can be seen from the picture, the time factor plays an important role in the C-QTc modeling. When the time factor was not included in the C-QTc analysis, the FNR was inflated in most models, except in the models with $\Delta\Delta\text{QTc}$ being the dependent variable. When the time effect was considered, the FNR was below 0.05 in most cases when $n=24$ or 36 .

Covariance structure has also played a significant role in controlling FNR. Based on the simulation results, the overall FNR under CS was lower than that for UN structure. For CS, the FNR can be controlled as long as the time factor was included into the model. When UN was used, the FNR can only be controlled when sample size was relatively large and time effect was either included into the model alone or included together with other variables if ΔQTc being the dependent variable (Fig. 3).

Based on this simulation study, the time effect should be incorporated into the model. Most models without the time effect would underestimate the true mean effect by more than 12%, but models with the time effect included

overestimate the true mean effect by no more than 2% and the small overestimation attenuated as sample size increased (Fig. 4).

Since FNR was not controlled by most base models, CP results were only presented for the covariate LMM models. As can be seen from Fig. 5, models that controlled FNR had CP at least 90%.

CONCLUSIONS AND DISCUSSION

The ICH E14 guidance^[4] provides recommendations to pharmaceutical companies in terms of how to conduct a TQT study. In practice, there is still a spectrum of encountered problems with details of design, conduct, analysis, and interpretation of such studies. In this entry, we have touched topics including correction methods for QT intervals by its heart rate, sample size, study design, assay sensitivity, time point selection, and baseline ECG collections. It is not required to double-blind the positive control arm, moxifloxacin, in TQT studies. There is no published research reported on data quality between blinded and open-labeled moxifloxacin data. If the study variability is smaller for double-blind moxifloxacin study, open-labeling moxifloxacin probably needs to be reconsidered. Before this issue becomes clear, we need to maintain the quality of the overall study design by double-blinding other

Fig. 3 False negative rate

Fig. 4 Relative bias when true $\Delta\Delta\text{QTc} = 10$ ms

treatment arms, which might require implementation of some special designs. For instance, for an even number of treatment arms, instead of using only one Williams square, we might need to use two or three Williams squares. A special “nested” crossover study within a parallel design is also discussed. The “nested” design can help reduce the larger sample size required for a parallel study, but the price to pay is more ECG collection.

It is well understood that the ICH E14 analysis is a conservative tool. If a negative conclusion is made for a compound, the chance of making a mistake for the QT risk is much smaller than 0.05. In recent years, researchers have been actively searching for other alternatives to replace TQT studies.

Garnett et al.^[46] proposed to assess treatment-induced QT prolongation by comparing the predicted one-sided 95% upper confidence interval of $\Delta\Delta\text{QTc}$ at mean $C_{\max}$ with 10 ms, which is done through a linear C-QTc model. Tsong et al.^[47] raised model fitness and other questions. The ICH E14 (Q&A) document^[48] emphasized the value of C-QTc modeling and indicated that C-QTc modeling is “an important component of a totality of evidence assessment of the risk of QT prolongation.” It further suggested that C-QTc modeling can be built into early phase studies as part of the conventional QT study. The ICH E14 (Q&A)

was revised in December 2015, enabling pharmaceutical companies to use a C-QTc modeling as the primary analysis for assessing QTc prolongation risk of new drugs.

The Consortium of Innovation and Quality in Pharmaceutical Development (IQ) and the Cardiac Safety Research Consortium (CSRC) collaborated to evaluate the C-QTc modeling in a small dose escalation clinical study.^[7,8] The joint IQ-CSRC study evaluated five QT-prolonging drugs and one negative drug in 20 healthy subjects. The results showed that C-QTc modeling made correct conclusions for all six drugs. However, as some researchers have pointed out,^[49] the IQ-CSRC study was not designed to assess false negative and false positive rates. The authors of this book entry also believe that IQ-CSRC did not provide enough evidence to show that C-QTc modeling is ready for the primary analysis based on five positive drugs and one negative drug. It makes sense to use the upper bound to exclude a positive compound under certain conditions; however, it is questionable to use the upper bound to judge if a compound is positive. The investigators in the IQ-CSRC study could make an even more “positive” claim by using a much smaller sample size or a badly or poorly designed study with a larger variability. From a safety point of view, it is acceptable to use the upper bound to exclude drugs with QT liability; however, we should also realize the risk of making

Fig. 5 Coverage probability for models with false negative rate controlled

a false-positive claim by using only the upper bound as the criterion, especially when the sample size is small. This topic is certainly worth further evaluation. However, it is not our intention to conclude that C-QTc modeling cannot be used. The authors strongly support the idea to use the C-QTc method in early drug development to help avoid unnecessary TQT studies for most negative compounds.

It is worthwhile to mention the difference between the C-QTc relationship approach discussed in Section V and the traditional C-QTc modeling that people are familiar with using. For the traditional approach, the conclusion is only based on one realization at mean $C_{\max}$, which by itself has a large variability.^[6] In addition, there are no statistical hypotheses that can be set up properly; therefore, no statistical power or optimal sample size can be obtained. It is not appropriate to compare the “power” between the traditional C-QTc modeling and ICH E14 analysis for a TQT study. The “power” used in the traditional C-QTc modeling does not have the same meaning as defined in a statistical analysis. Even though nothing is wrong with calculating upper or lower bounds at any concentration level, one needs to realize the limitations of the conclusions that may be drawn. Also, the results between the traditional C-QTc approach and the ICH E14 findings do not always agree. Florian et al.^[50] published analysis results using moxifloxacin data based on 20 TQT studies submitted to the FDA. Using C-QTc modeling, the predicted one-sided 95% upper confidence interval for moxifloxacin at $C_{\max}$ was less than 10 ms in two studies, which was not consistent with

the results by ICH E14 analysis. The false negative rate was 10%. The largest mean difference between ICH E14 and C-QTc in one study was as large as 4.4 ms.

In this entry, we present a modified C-QTc model. The performance of this new model was evaluated through a simulation study. The authors believe that the time factor is critical to the modeling and should be included in a C-QTc model in order to control false negative rate. In light of the recent update of the ICH E14 (Q&A), careful consideration needs to be given to a study where C-QTc is used as primary analysis in order to control false negative rates.

There is still room to improve the current C-QTc approach.

Tiered Approach of Analytical Similarity Assessment: Statistical Methods

Yi Tsong

Office of Biostatistics, Office of Translational Science, CDER, FDA, Silver Spring, Maryland, U.S.A.

Abstract

For approval of a biosimilar drug product, the U.S. Food and Drug Administration recommends a stepwise approach for obtaining the totality of the evidence between the proposed biosimilar product and its corresponding innovative biological product be considered. The stepwise approach starts with the assessment of similarity in identified critical quality attributes, which are classified into three tiers depending upon their corresponding criticality or risk ranking relevant to clinical outcomes. Appropriate statistical tests (e.g., equivalence test, quality range approach, and raw data graphical presentation) are then applied to these critical quality attributes in different tiers (e.g., Tier 1, Tier 2, and Tier 3, respectively). This article intends to provide an overview of these statistical tests for analytical similarity assessment in biosimilar studies.

Keywords: Equivalence test; Raw data graphical presentation; Tiered approach; Totality of the evidence; Quality range approach.

BACKGROUND

As defined in 351(i) of the Public Health Service (PHS) Act, biosimilarity is “that the biological product is highly similar to the reference product notwithstanding minor differences in clinically inactive components” and that “there are no clinically meaningful differences between the biological product and the reference product in terms of the safety, purity and potency of the product.” For the assessment of biosimilarity for biosimilar products, the U.S. Food and Drug Administration (FDA) published a few guidances. As indicated in its recent guidance, the FDA recommends a stepwise approach for obtaining the totality of the evidence for demonstrating biosimilarity between a proposed biosimilar product and an innovative (reference) biological product.^[1–3] The stepwise approach starts with analytical studies for functional and structural characterization of critical quality attributes (CQAs) that are relevant to clinical outcomes at various stages of the manufacturing process followed by animal studies for the assessment of toxicity, clinical pharmacology pharmacokinetic (PK) or pharmacodynamic (PD) studies, and clinical studies for the assessment of immunogenicity, safety/tolerability, and efficacy (see Fig. 1).

Analytical similarity serves as the foundation of biosimilarity assessment. CQAs in the manufacturing process of drug products are referred to as chemical, physical, biological, and microbiological attributes that can be defined, measured, and continually monitored to ensure the finished products remain within acceptable quality limits. For the analytical studies, CQAs should be identified and classified into three tiers according to their criticality or risk ranking based on the mechanism of action or PK. A few CQAs that are most relevant to clinical outcomes will be classified as Tier 1, those that are least relevant to clinical outcomes or non-numerical ones will be classified as Tier 2, and the rest will be classified as Tier 3, respectively.^[3,4] Accordingly, we proposed different statistical approaches for the different tiers of the CQAs.

STATISTICAL APPROACHES USED FOR ASSESSING SIMILARITY

In analytical similarity assessments, an extensive structural and functional characterization of both the proposed biosimilar product and the reference product is conducted. Considering practicality, a three-tiered statistical approach for utilizing various statistical methods was proposed to evaluate analytical similarity data. The quality attributes (QAs) should be ranked depending on the risk of the attributes based on their potential impacts on clinical activity, PK/PD, safety, and other factors. In general,

Note: This article reflects the views of the author and should not be construed to represent the FDA's views or policies.

Fig. 1 A stepwise approach for demonstration of biosimilarity

statistical equivalence test is proposed to apply to some of the selected highest ranked QAs; quality range statistical approach is proposed to assess the analytical similarity of other selected high-ranked quantitative QAs; side-by-side comparison approaches are proposed for the rest QAs. In the following subsections, we will present more details of the statistical approaches, especially for Tier 1 statistical approach. Overall, the equivalence test approach proposed for Tier 1 CQAs is more rigorous than the quality range approach proposed for Tier 2 CQAs, which is statistically more rigorous than the side-by-side graphic comparison approach for Tier 3 CQAs, in terms of the stringency of the approaches for its study objective. It should not be interpreted as if a CQA that satisfied the equivalence test proposed for Tier 1 CQA would also satisfy the criteria of the quality range approach proposed for Tier 2 CQAs.

STATISTICAL EQUIVALENCE TEST FOR TIER 1 CQAS

Similar to the bioequivalence testing for generic drugs,^[5] for Tier 1 CQAs, equivalence in means between the proposed biosimilar and reference products can be measured either by the ratio of means or by the difference of means. Here, for simplicity to illustrate, let us focus only on the normally distributed data and difference of product means. The two one-sided hypotheses can be written as follows:

$$\begin{aligned} H_{01} : \mu_T - \mu_R \leq -\delta & \quad \text{vs.} \quad H_{a1} : \mu_T - \mu_R > -\delta \\ H_{02} : \mu_T - \mu_R \geq \delta & \quad \text{vs.} \quad H_{a2} : \mu_T - \mu_R < \delta \end{aligned} \quad (1)$$

where $\delta > 0$ is the equivalence margin. More details of the choice of δ values will be presented in the later section. Based on the properties of two one-sided tests (TOSTs), the familywise type I error rate is controlled at $\alpha = 0.05$ if each of the two one-sided hypotheses H_{01} and H_{02} is tested at $\alpha = 0.05$ separately.

With a proper design, for each CQA to be analyzed, there are J replicates of the testing results from each of the n_T biosimilar lots and from each of the n_R reference lots. Let σ_{Ti}^2 and σ_{Ri}^2 be the variances of the i th biosimilar lot and i' -th reference lot, respectively. Let X_{Ti} $X_{Ri'}$ be the

lot sample mean value of replicates within each lot for test and reference, respectively. For the following discussions, X_{Ti} and $X_{Ri'}$ are assumed to follow $N(\mu_T, \sigma_T^2)$ and $N(\mu_R, \sigma_R^2)$ distributions, respectively.

Note that when there are J replicates in each of reference and biosimilar lots, X_{Ti} and $X_{Ri'}$ represent the sample means of J replicates and they have the variance $\sigma_k^{*2} = \frac{1}{J} \sigma_{kiJ}^2$ where $k = T$, and R and σ_k^{*2} represents the true value between lot variances. For simplicity, we assume that $\sigma_k^2 = \sigma_k^{*2} + \frac{1}{J} \sigma_{kiJ}^2$ with equal σ_{kiJ}^2 across all lots.

For testing against H_{01} and H_{02} , the following test statistics are used:

$$T_1 = \frac{(\bar{X}_T - \bar{X}_R) + \delta}{\sqrt{\frac{S_T^2}{n_T} + \frac{S_R^2}{n_R}}}, T_2 = \frac{(\bar{X}_T - \bar{X}_R) - \delta}{\sqrt{\frac{S_T^2}{n_T} + \frac{S_R^2}{n_R}}}, \quad (2)$$

where $\bar{X}_l = \sum_{i=1}^{n_l} X_{li} / n_l$, $S_l^2 = \sum_{j=1}^{n_l} (X_{lj} - \bar{X}_l)^2 / (n_l - 1)$; X_{li} is the lot attribute value, estimated by the average of the replicates within the j th lot for product l , $l = T, R$; and n_T and n_R are the number of lots from the proposed biosimilar and reference products, respectively. Please note that the expectation of S_l^2 is a linear combination of both within- and between-lot variances, and it decreases toward σ_i^2 when the number of replicates increases within each lot.

Under the null hypotheses, when the margin is a known constant, T_1 and T_2 follow an approximate t -distribution with v degrees of freedom, where v is approximated by Satterthwaite^[5] as follows:

$$v = \left(S_T^2 / n_T + S_R^2 / n_R \right)^2 / \left(\left(S_T^2 / n_T \right)^2 / (n_T - 1) + \left(S_R^2 / n_R \right)^2 / (n_R - 1) \right)$$

On the boundary of H_{01} , $T_1 \sim t_v$, where t_v is the t -distribution with a degree of freedom v . On the boundary of H_{02} , T_2 follows the same distribution as T_1 . Thus, H_{01} and H_{02} of Eq. 1 are rejected with the conclusion of statistical equivalence in means if $T_1 > t_{v,0.95}$ and $T_2 < t_{v,0.05}$.

The above hypothesis testing approach is consistent with the decision rule of using the $(1 - 2\alpha)$ 100% two-sided confidence interval of the mean difference under normality, and σ_R in the equivalence margin is assumed to be known or determined using exterior information. For normally distributed attributes, the two one-sided hypotheses (Eq. 1) are used to test for the following equivalence hypothesis:

$$\begin{aligned} H_0 : \mu_T - \mu_R \leq -\delta \text{ or } \mu_T - \mu_R \geq \delta \\ H_a : -\delta < \mu_T - \mu_R < \delta \end{aligned} \quad (3)$$

Analytical similarity is supported if the null hypothesis H_0 of Eq. 3) is rejected. In other words, statistical equivalence in means is established if we can show that

$-\delta < \mu_T - \mu_R < \delta$ by using the test statistics in Eq. 2 or by showing that $(\bar{X}_T - \bar{X}_R) \pm t_{1-\alpha, \nu} \sqrt{S_T^2/n_T + S_R^2/n_R}$ is completely contained within the interval $(-\delta, \delta)$.^[6]

Note that when the attribute value Y follows a lognormal distributions, we may use $X = \log(Y)$ which has a normal distribution for the equivalence test.

QUALITY RANGE APPROACH FOR TIER 2 CQAS

For the selected QAs (CQAs) of Tier 2 category, the similarity assessment is focused on the data spray of biosimilar product against the reference product. For this reason, instead of evaluating the equivalence of means of the lot attribute values, the objective is to show that the biosimilar data overlap with the reference product well within a reasonably defined range of its qualities. The basic concept of this statistical approach is that it requires a large proportion, say 90%, of the test results from the biosimilar lots to be within an acceptance range determined by the reference product. Assume the test results of the reference product follow the normal distribution as defined earlier, e.g., $X_R \sim N(\mu_R, \sigma_R^2)$, then a certain proportion of the observations from the reference product can be found within the interval of $\mu_R \pm k \times \sigma_R$. Let us name this interval of $\mu_R \pm k \times \sigma_R$ as the quality range. For example, there is about 68% coverage of all lot values of the reference product within the interval of $\mu_R \pm \sigma_R$; there is about 95% coverage of the reference distribution within $\mu_R \pm 2\sigma_R$; there is about 99.7% coverage within $\mu_R \pm 3\sigma_R$; and there is about 99.99% coverage of the reference distribution within $\mu_R \pm 4\sigma_R$. The problems of precise estimation of the range with small sample size are well known. The mean $\pm k$ SD approach uses the point estimate of the target interval with the intended coverage. This approach has its own statistical issues and limitations, especially when the data are clearly not normally distributed. However, as it is often used in specification determination in the early development stage and is also used in an appropriate quality control chart, chemists and biologists can easily understand the mean $\pm k$ SD approach better than any other alternative range approach. The determination of using an alternative multiplier k would mainly depend on scientific judgment.

GRAPHIC AND RAW DATA COMPARISON FOR TIER 3 CQAS

Graphic and raw data comparison approaches are often used for Tier 3 CQAs. The approaches are often chosen for information presentations in a multivariate nature. Due to the lack of rigidness of the approaches in statistical properties, the potential of being subjective and biased is usually large. These approaches are chosen because they have less impact on CQAs with less impact on clinical outcomes in

the sense that a notable dissimilarity will not affect clinical outcomes. The results of these approaches are more suitable to characterize the similarity or dissimilarity between biosimilar and reference products that is not attainable using the parameters to represent the information.

DETERMINATION OF EQUIVALENCE MARGIN

As in any equivalence test, determination of a proper equivalence margin is crucial and yet challenging. Preferably, a biologically or clinically meaningful equivalence margin may be derived from scientific knowledge or past experience. However, such a predefined margin is not available for biosimilar development programs most of the time. Furthermore, a one-size-fits-all margin may not be suitable to serve as an acceptance criteria for QAs due to the following reasons: (1) a biosimilar application may have multiple selected CQAs with difference variability to be analyzed using the equivalence test. Using a fixed margin, it can lead to a requirement of different sample sizes (number of lots) for each QA. Sometimes, the required sample size may be much larger than what is practically possible. (2) Different biosimilar development programs with a common reference product may have different QAs selected for using the equivalence test or may apply different analytical methods for the same QAs. Thus, a unified but not fixed margin is needed. (3) The sample size (number of lots) available in the analytical similarity studies is usually very limited and pre-given. Thus, analytical similarity studies with small sample sizes would have a low power to pass the equivalence test using a one-size-fits-all margin unless the margin is overly wide. Therefore, the development of a statistical equivalence margin is helpful when a biologically or clinically meaningful margin is not available.

Due to the properties of the biologics and the unique challenges in analytical similarity assessment, the statistical equivalence margin was derived with the following considerations: first, a unified representation of the margin is needed for all selected CQAs with a different variability, and second, a margin needs to be determined by achieving a sufficient power of passing the equivalence test with the practically limited sample sizes. With these two considerations in mind, it led to an equivalence margin as a function of the reference product variability.

Under the equal sample size and equal variance assumption, Limentani et al.^[7] recommends a margin determination for analytical chemistry. That is,

$$\delta = \delta_0 + s^* \left[t_{(1-\alpha, 2n-2)} + t_{(1-\beta/2, 2n-2)} \right] \sqrt{2/n}, \quad (4)$$

where δ_0 is a prespecified tolerable shift, s^* is the upper 95% confidence limit of standard deviation of the reference product, and $t_{(a,b)}$ is the 100 a th percentile of t -distribution

with b degrees of freedom. Limentani et al.^[7] recommended using $1 - \beta/2 = 0.99$ for any sample size at the alternative hypothesis $\mu_T - \mu_R = \delta_0$. Therefore, the Limentani approach defines the margin as a function of s^* to have 99% power to pass equivalence test for any sample size if the true mean difference is no larger than a prespecified difference of δ_0 . In general, this margin is considered to be too wide, especially for small sample sizes. The Limentani approach does not reward large sample sizes, thus providing little motivation to increase the sample size.

To overcome the caveat of the Limentani approach, an equivalence margin δ is considered as a function of the variability of the reference product with a form of $\delta = f \times \sigma_R$. The multiplier f is adjusted by the sample size and the power. In our approach for determination of f , the first step is to preassign the power as a monotonic increasing function of the sample size under a given true mean difference, the target “similarity.” The second step is to obtain the margin to achieve the preassigned power at the first step with the given sample size and true mean difference. In practice, σ_R is unavailable to both the biosimilar sponsor and the regulatory agency. Conventionally, the sample standard deviation is used as the estimate of the variability in margin determination. The related statistical issues will be discussed in later sections.

As mentioned earlier, for most of biosimilar development programs, the sample size is usually limited. Ten lots per product is generally considered feasible. With such a practical issue, more than 60% power is allocated to pass the equivalence test at the assumed true mean difference when the number of lot is less than 10. The possible power values assigned to different sample sizes with biologists were derived through internal discussion in the FDA with various disciplines involved; the initial power values assigned to the given sample sizes that may cover extremely small to moderate sample sizes in biosimilar development are provided in Table 1.

To generalize the power to any number of lots, a monotonic exponential function was fitted through the five values in Table 1. The fitted curve is

$$\text{Power}(n) = 1 - \exp(-0.53948 - 0.14694n + 0.00205n^2). \quad (5)$$

With this monotonic function, the fitted power curve of the power is shown in Fig. 2.

Table 1 Initial power assignment for the given number of lots assuming the true mean difference meets the “targeted” similarity criteria

Number of lots per product	Assigned power (%)
6	72
10	85
15	90
20	92
25	95

Fig. 2 Fitted curve of assigned power as a function of the number of lots per product assuming the true mean difference meets the “targeted” similarity criteria

Next, a target similarity criterion Δ_0 to determine the multiplier f for the margin $\delta = f \times \sigma_R$ is derived using the power calculation. The two one-sided equivalence test hypotheses become

$$\begin{aligned} H_{01} : \mu_T - \mu_R \leq -f \times \sigma_R & \text{ vs. } H_{a1} : \mu_T - \mu_R > -f \sigma_R \\ H_{01} : \mu_T - \mu_R \geq f \times \sigma_R & \text{ vs. } H_{a1} : \mu_T - \mu_R < f \sigma_R \end{aligned} \quad (6)$$

The corresponding two tests are

$$T_1 = \frac{(\bar{X}_T - \bar{X}_R) + f \times \sigma_R}{\sqrt{S_T^2/n_T + S_R^2/n_R}}, T_2 = \frac{(\bar{X}_T - \bar{X}_R) - f \times \sigma_R}{\sqrt{S_T^2/n_T + S_R^2/n_R}}.$$

For the objectives as described, a target similarity criterion Δ_0 is identified in order to determine the multiplier f for the margin $\delta = f \times \sigma_R$ using the power calculation. The sample size–power function for TOST with equal sample sizes and equal variance assumption when is derived for the target mean difference Δ_0 is $\eta \times \sigma_R$ and the equivalence margin is $f \times \sigma_R$, where σ_R is assumed to be the known standard deviation of the reference product:

$$\begin{aligned} \text{Power}(n) &= \Pr(T_1 > t_{1-\alpha, 2(n-1)}, T_2 < t_{\alpha, 2(n-1)}) \\ &= E_{U^2} \left[\Phi \left(\frac{f - \eta}{\sqrt{2/n}} - t_{1-\alpha, 2(n-1)} \sqrt{\frac{U^2}{2(n-1)}} \right) \right. \\ &\quad \left. - \Phi \left(\frac{-f - \eta}{\sqrt{2/n}} + t_{1-\alpha, 2(n-1)} \sqrt{\frac{U^2}{2(n-1)}} \right) \right] \end{aligned} \quad (7)$$

where U^2 follows the chi-square distribution with $2(n-1)$ degrees of freedom, Φ is the cumulative probability function of the standard normal distribution, and E is the expectation with respect to U^2 . The power curves are generated for $\eta = 1/16, 1/8, 3/16, 1/4, 5/16$, and $1/2$. After

Table 2 Proposed multiplier f for the margin $\delta = f \times \sigma_R$ to achieve the assigned power with a true mean difference of $1/8 \sigma_R$ and $\alpha = 0.05$ with the given number of lots per product n

	$n = 6$	$n = 7$	$n = 8$	$n = 9$	$n = 10$	$n = 11$	$n = 12$	$n = 13$	$n = 14$	$n = 15$
Assigned power (%)	74	77	79	82	84	85	87	88	89%	90%
f	1.74	1.64	1.55	1.50	1.45	1.39	1.36	1.33	1.30	1.27
	$n = 16$	$n = 17$	$n = 18$	$n = 19$	$n = 20$	$n = 21$	$n = 22$	$n = 23$	$n = 24$	$n = 25$
Assigned power (%)	91	91	92	93	93	93	94	94	94	95
F	1.25	1.21	1.20	1.19	1.16	1.13	1.13	1.11	1.09	1.09

carefully studying the results with representatives of all related disciplines in the FDA, the target mean difference Δ_0 is selected as $1/8 \sigma_R$. Then, under $\Delta_0 = 1/8 \sigma_R$, the corresponding multiplier f values in the equivalence margin of $\delta = f \times \sigma_R$ to achieve the assigned power calculated using Eq. 7 are listed in Table 2. The table shows that the multiplier f decreases with an increase in the sample size. When the sample size is small, the equivalence margin is wider compared to that for the larger sample size. However, this does not mean that the acceptance criteria of analytical similarity are easier for small sample sizes. Smaller sample sizes are adequately justifiable if the product is available for small patient population.

Keep in mind that the power of passing the equivalence test is controlled at lower levels for small sample sizes although the margin appears to be wider. In order to make the implementation of the equivalence test easier, the same value of the multiplier f for all sample sizes may be needed but adjusted for the value of α instead. For this objective, $n = 10$ is selected as the reference point and $f = 1.5$ is assigned instead of 1.45 for the margin. This increases the power from 84% to 87% when using $\alpha = 0.05$. The power values assigned to other sample sizes also slightly change.

Finally, the equivalence margin as $\delta = 1.5 \times \sigma_R$ is chosen by an FDA committee of various disciplines. Correspondingly, the two one-sided equivalence hypotheses become

$$\begin{aligned} H_{01} : \mu_T - \mu_R &\leq -1.5\sigma_R \text{ vs. } H_{a1} : \mu_T - \mu_R > -1.5\sigma_R \\ H_{02} : \mu_T - \mu_R &\geq 1.5\sigma_R \text{ vs. } H_{a2} : \mu_T - \mu_R < 1.5\sigma_R \end{aligned} \quad (8)$$

As mentioned earlier, the equivalence test can also be performed by comparing the $(1 - 2\alpha)$ 100% two-sided confidence interval of the mean difference against the equivalence margin, where $(1 - 2\alpha)$ 100% is the confidence level. When applying the power function (Eq. 7) with a margin of $1.5\sigma_R$, the confidence levels required are derived for each equal sample size from 6 to 15 and listed in Table 3.

ISSUES OF THE PROPOSED STATISTICAL APPROACHES FOR TIER 1 CQAS

There are potential issues regarding our proposed statistical equivalence test for Tier 1. First, let us examine the

Table 3 Confidence level with $\delta = 1.50\sigma_R$ for various sample sizes

Number of lots per product	Margin	Assigned power at mean difference of $1/8\sigma_R$ (%)	Confidence level (%)
6	$1.50\sigma_R$	78	78.4
7		82	81.4
8		84	85.0
9		86	87.4
10		87	90.0
15		90	90.0

underlying assumptions to ensure proper statistical properties of our proposed equivalence testing. The first assumption is that the samples are randomly selected and are representative of the product. In practice, the reference lots are purchased from the market with unknown manufacturing dates. If the reference lots are selected from a wide period of manufacturing dates, then it is likely to have proper estimate of reference variability of the whole population of reference lots. In contrast, if the reference lots are chosen from a correlated sample, e.g., successive lots may use some materials in common, then the test results may not be representative of the product or the variability can be underestimated and the mean estimate may also be biased. Using a random-effects model to adjust for the variance based on the small sample of lots may be biased. On the other hand, the biosimilar lots are usually freshly produced with known manufacturing dates and known manufacturing process. Thus, more knowledge of the biosimilar variability will be attained in the future. But in the same way as the reference sample, the sample mean and variance may not represent the population of biosimilar lots to be manufactured in the future. For details of the discussion, please refer to the works of Burdick et al.,^[8] Tsong et al.,^[9] and Shen et al.^[10]

The second assumption of the proposed equivalence testing is that the standard deviation σ_R for the margin determination is a known parameter. In practice, σ_R is usually unknown and is estimated from samples. For this reason, using estimate as constant may have the impact on type I error rate and power. This issue is also studied

and reported separately by Burdick et al.,^[8] Dong and Weng et al.^[11]

In addition, the lot value X is often the average of k replicates within the same lot. Then, X would have a mean value of μ_i and a variance of $\sigma_a^2 + \sigma_e^2/k$, where σ_a^2 and σ_e^2 are the between- and within-lot variances, respectively. As discussed earlier, the variance of $\bar{X}$ (i.e., the sample mean value across different lots) is a linear combination of those two variance components; then its value reduces with an increase number of replicates within the lot. The expression of variance of $\bar{X}$ could be more complicated if the within-lot variance is different from lot to lot. For some detailed discussion, please refer to the work of Tsong et al.^[13]

The third unstated assumption is that the data are considered blind if they are analyzed only once. In reality, more samples may be added in a later stage before Biologics License Application submission. In addition, the number of reference lots can be much larger than the number of biosimilar lots, because purchasing sufficient reference lots from the market is the first step in the biosimilar development. Thus, the sample size imbalance may cause some concerns in analytical similarity evaluation for Tier 1. Dong et al.^[14] describe those concerns and the potential statistical approaches to addressing the issues.

As described earlier, the multiplier 1.5 in the proposed equivalence margin is determined based on an assumed mean difference of $\mu_T - \mu_R = \sigma_R/8$. Both the assumed mean difference and the multiplier, 1.5, were selected based on power simulation results. These values may need to be revised when the statistical approaches are updated in the future.

Abstract

In the typical titration study, the response is defined according to some predetermined criterion, the dose is increased over time, and a subject may receive more than one dose level. This entry provides reasons and rationale for utilizing titration design in clinical trials as well as a sample data analysis.

INTRODUCTION

One of the most critical and challenging tasks in developing a new drug is to determine a dose range that provides an optimal therapeutic risk/benefit ratio in the targeted population. Clinical trials carried out to explore this optimal dose range can be grouped into two types of study design.

The *parallel-groups, fixed-dose* study is the first type of design. It is the simplest and most commonly used design to explore the dose range. In the parallel study, subjects are randomly assigned to receive one of a set of predetermined doses for the entire study duration. No dose adjustments are allowed, so a subject receives only one dose level.

The *dose titration* study is the second type of design. In this study, all subjects are started on the lowest of a pre-specified set of dose levels. Subjects who respond on the lowest dose stay on that dose; those who do not respond on the lowest dose after a fixed treatment period receive the next highest dose. This procedure is repeated until all subjects either drop out, respond, or reach the highest dose level.

OVERVIEW

In the typical titration study, the response is defined according to some predetermined criterion, the dose is increased over time, and a subject may receive more than one dose level. Variations on the typical titration design include the use of a concurrent placebo group, the titration of the dose level up or down, and a forced titration, in which all subjects receive a higher dose regardless of their response at a lower dose, assuming they do not drop out for safety or other reasons.

The layout of the parallel design is:

The layout of the titration design is:

The fundamental difference between a titration study and a parallel study is that in a titration study, a subject receives a higher dose only if the subject fails to respond at a lower dose. At each titration step, the target populations are different. For example, in a parallel study, the target population for subjects who receive dose level 2 is all subjects who have the disease. In a titration study, the target population for subjects who receive dose level 2 is all subjects who have the disease but failed to respond on dose level 1. Thus the target populations at dose level 2 are different in each study. This is why the proportion of responders at a particular dose level in a parallel study should not be compared directly with the proportion of responders at that same level in a titration study. It is also the main reason why the analysis and the interpretation of a titration study are more complicated than that of a parallel study.^[1,2]

In general, if the purpose of the study is to compare the drug as a whole to placebo, then titration can provide a clear evidence of effectiveness and valuable information on population average and individual dose–response relationships.^[3] If the purpose of the study is to compare several doses to placebo, then the use of titration makes it more difficult to evaluate the effect of the drug by dose, and a careful analysis is needed.

USE OF TITRATION DESIGNS

Clinical Rationale

In certain circumstances, a titration design is desirable and sometimes even necessary for clinical reasons. In a titration study, subjects are exposed only to the amount of drug necessary to control their disease. This is good clinical practice and is the main reason to titrate the dose. Titration studies also provide information on the sequential and cumulative effects of the drug, so they are often used in clinical trials with drugs intended for long-term use at varying dose levels, such as antihypertensive drugs. Titration designs are also used in clinical trials in evaluating formulations of insulin for diabetic subjects, because it is usually necessary that the dose for each individual subject be titrated up or down until the desired response is reached. Titration may also be necessary because a subject may build up tolerance to a drug. For example, when taking an alpha blocker, a subject's dose level may need to be increased gradually to avoid orthostatic hypotension.

Even if titration appears to be appropriate for clinical reasons, the following requirements are necessary for the appropriate use of a titration study:

1. The response to the titration must be well-defined and easily measurable.
2. The number of dropouts cannot be excessive.^[3]
3. The cumulative effect of the drug must be minimal.^[3]
4. The time until the response develops must be relatively short. For example, in a hypertension study, the response might be a decrease in supine diastolic blood pressure to 90 mm Hg or less, which is sustained over a 2-week period.^[1,3]
5. If the response to a titration is irreversible, such as cure of a bacterial infection, then the use of a titration design is not appropriate.^[3]
6. Titration designs may not be suitable in diseases such as osteoporosis, Alzheimer's disease, or depression, because a desired response may develop only after a long period of time, and even if the treatment period is extended, the response may be difficult to measure.

Disadvantages of Titration

In a typical titration study, the dose is confounded with the duration of treatment because a lower dose is always followed by a higher dose. Over the course of treatment, the disease may progress, the subjects may exhibit spontaneous improvement, or the drug may have some cumulative effects. As a result, dose and time effects are hard to separate. One of the key issues in a titration study therefore is deciding when to titrate the dose. If the dose is titrated upward before its full effect is realized, the subject will be exposed to a level of drug that is unnecessarily high, and thus the recommended dose will be overestimated. This can happen in a confirmatory study where the goal is to compare the efficacy of several doses, or when a high dose is considered appropriate because of the urgent need for an effective treatment. In cases where the dose-related toxicity is relatively small and there is no safety incentive to minimize the dose, a likely tendency is to choose the highest dose that is reasonably well tolerated. Freston^[4] presented several examples of this tendency in hypertension studies. In another example, given by Temple,^[5] one-twelfth of the highest dose level used in a titration study was eventually considered to be the maximum effective dose. This problem can be minimized somewhat by extending the treatment time on each drug level.

With some drugs, a carryover effect may exist from one dosing period to another. In a titration study, because the doses are given in increasing order, these carryover effects may be harder to estimate than in other types of designs. For example, in a crossover study, subjects are given several different levels of drug, but in a preset random order rather than in a strictly increasing order. In general, however, crossover studies and titration studies are used to answer different questions.

Advantages of Titration

Titration designs provide practical as well as statistical advantages. The main practical advantages of titration designs are that they are in accordance with good clinical practice, they allow subjects to be exposed only to the amount of drug necessary to control their disease, and they mimic the way the drug will be prescribed. One statistical advantage is that because each subject may receive more than one dose, titration designs can provide information on the distribution of individual dose–response curves as well as on the population-average, dose–response curve. Another statistical advantage is that titration studies can be used to examine the response over a wide range of doses, usually with a smaller number of subjects, than a parallel study with the same statistical power.^[1,2,3] Sheiner et al.^[6] compared parallel, crossover, and titration designs in dose-ranging studies. They concluded that if a

patient-specific parametric dose–response model is used, then a titration study can be more advantageous than either a parallel study or a crossover study.

Titration designs are useful in phase I tolerance trials, in which the goal is to assess the safety of the drug. They are also valuable in early phase I/II exploratory studies, when the drug is assumed to have an effect but little is known about the dose–response relationship.^[1,7] In these studies, the goal is to examine the effectiveness of the drug over a wide range of doses, and to define the shape of the dose–response curve. Thus the titration design may be helpful in choosing doses for a later, confirmatory parallel study, in which hypotheses about the drug’s efficacy are tested.^[3]

Titration designs are also appropriate in phase III randomized trials if the intended way for the drug to be prescribed is in a titration scheme. An additional benefit in this case is that subjects used in phase III studies more closely resemble the target population of subjects with the disease. With the inclusion of a placebo group and appropriate analysis, these later-stage titration studies can also provide pieces of evidence of the safety and overall efficacy of the drug as well as evidence of the effectiveness of various doses.^[8]

ANALYSIS OF A TITRATION DESIGN

Types of Analysis

Life Table Approach

In the discrete life table approach to the analysis of a titration study,^[1] three general assumptions are made. First, the period during which one dose is administered is long enough for the physiological systems to stabilize. Second, a subject who responds at one dose will respond at all higher doses. Third, given the number of subjects who receive a particular dose, the number of responders at that dose follows a binomial distribution. The probability of response in that binomial distribution is a conditional probability, given that the subject failed to respond at all lower doses. If all three assumptions are satisfied, then a relationship exists between the unconditional probability of response at a particular dose level, as commonly defined in a parallel study, and the conditional probability of the titration study. This method of analysis resembles a life table approach in that the end event is defined by the response to the drug and the follow-up periods by the dose level.

In Chuang’s life table approach, a logistic linear model is used to define the dose–response relationship. The parameters in the model are estimated using iterated reweighted least squares, and the procedure is applied to the study of an antihypertensive compound.

Life table estimates can be imprecise, however, if subjects in the titration study skip doses, receive too high a dose, or receive a low dose after a high dose. Shih et al.^[8] address these problems in the analysis of a phase III study.

Incomplete Design Approach

The incomplete design approach to the analysis of a titration study^[9] generalizes Chuang’s life table approach. In a complete design, all subjects are exposed to all dose levels. The titration design can be viewed as an incomplete design because all subjects are not exposed to all doses. Wong^[9] also provides estimates of lower and upper bounds for the unconditional probabilities of response.

The assumption that a subject who responds at one dose will respond at all higher doses is not made in the incomplete design approach. If this assumption is included, however, the estimates from the life table and incomplete design approaches will be the same. As in the life table approach, dropouts are assumed to occur at random.

Contingency Table Approach

Once a dose–response relationship has been established in phase I/II clinical trials, efficacy and safety are confirmed in phase III. A phase III titration study can be used to determine if the overall response rate is satisfactory, the starting dose is therapeutically useful, and a maximally effective dose is reached whether or not one titrates up to the high dose.

Shih et al.^[8] analyze the data in a phase III antihypertensive study as a one-dimensional contingency table including incomplete (grouped) information on the number of dropouts at each dose level, obtaining maximum likelihood parameter estimates through the EM algorithm. They do not require knowledge of the number of subjects who receive a particular dose level as in the life table approach, but only of the lowest dose level to which each subject responded before withdrawal. This is because in large phase III titration studies, even if the design is well defined, nonresponders may skip steps in the titration scheme, or responders may be escalated to an unnecessarily high dose or even have their dose reduced. The EM algorithm is not affected by these irregularities, but the life table approach can be affected.

As in the life table approach, it is assumed that the dropouts are withdrawals between two successive doses and that their censoring mechanism is independent of efficacy. A method for incorporating dropouts into the efficacy evaluation is given by Chuang-Stein and Shih.^[10]

Titration with Placebo Controls

If a placebo effect is expected to be high, the magnitude of the effect as well as the efficacy of the drug as a whole can be estimated by the inclusion of a placebo control group. If placebo controls are included concurrently with each dose group, the effect of the dose can be measured relative to the placebo controls for that dosing group.

Chuang-Stein^[7] extended her life table approach to include a placebo control. She used logistic linear models and iterated reweighted least squares in two approaches to compare the responses of the test drug groups to those of the placebo controls. In the first approach, similar models were assumed for both the drug and the control groups. In the second approach, it was assumed that the response rates of the test drug groups were consistently higher than those of the placebo groups, and the response rates were evaluated relative to those of the corresponding placebo groups.

Pun^[2] compared and contrasted parallel and titration dose-ranging studies. He recommended the inclusion of a concurrent placebo group in a titration design in order to investigate the risk/benefit ratio for subjects who do not respond to a lower dose and must be titrated up to a higher dose. He showed that for a fixed sample size, the titration design has more accuracy and power in determining the dose range than does the parallel design.

Analysis of Safety Data

Even the response is easily measurable and occurs in a short period of time, the analysis of safety data in a titration study presents special problems, and the estimation of the risk/benefit ratio is more challenging. The incidence of an adverse event is usually defined as the proportion of subjects who experience the event at a given dose. Because the effect of the drug is confounded with time, the pattern of occurrence of an adverse event or a laboratory abnormality might be mistaken for a drug effect. For example, suppose a particular adverse event tends to occur early in drug treatment. As the dose is titrated upward, the incidence of the adverse event gets smaller, mistakenly indicating a negative dose effect.

In addition, the assumptions in analyzing the safety data in a titration study are not the same as those in analyzing the efficacy data. A necessary assumption in most analyses of efficacy data in a titration study is that a subject who responds at one dose level will respond at all higher dose levels. If a subject experiences an adverse event at one dose level, however, it does not imply that the subject would have experienced the same adverse event at all higher dose levels. It also does not imply that increasing the dose necessarily makes the adverse event worse, although sometimes this is true. For example, suppose a subject experiences a headache on the lowest dose level and dizziness on the next higher dose level.

The dizziness may be due only to the time on drug and not to the higher dose level. That is, dizziness would have been experienced in the second treatment period even if the subject had not been titrated up to the higher dose. On the other hand, a side effect that appears on one dose level but disappears at a higher dose level may be due to the subject's having adjusted to the pharmacological effect of the drug and not to the higher dose level. Thus the analysis of safety data in a titration study presents special problems.

Hsu and Laddu^[11] state that because of the pattern of occurrence of adverse events in a titration study, no dose-specific evaluation of adverse events can be made. In order to evaluate the time trend, they recommend the inclusion of a placebo control group, the dose level, the time of occurrence of the adverse event, and the speed of titration. They also recommend the comparison of the results to those from a parallel study.

CONCLUSION

Parallel and titration designs are used extensively in dose-finding and comparative studies. The basic difference between them is that they are used to answer different questions.^[2,8,12] Parallel studies are useful in determining the effectiveness of various doses through the use of independent dose groups having the same duration of treatment, in anticipation of fixed-dose, short-term prescriptions. Titration studies provide information on the sequential and cumulative effects of the drug at various dose levels, and are useful when the drug will be prescribed for long-term use at varying dose levels.^[8]

When titration designs are used and analyzed appropriately, they can provide valuable information on the safety and the efficacy of the drug. By including a concurrent placebo group and taking into account the dose, time, and speed of titration, the titration design can provide information on the overall safety and efficacy of the drug as well as on the effect by dose, but the results for each individual subject remain somewhat confounded by time.^[3,11,13,14]

Abstract

Toxicology is defined as the knowledge of harmful effects of chemical substances on living organisms. The focus of this entry is on detailing several testing methods for determining toxicology and also stresses the importance of statistical analysis being performed before the study itself.

INTRODUCTION

Toxicology is defined as “the knowledge of harmful effects of chemical substances on living organisms.” The methods of toxicology are used to assess the potential risk of substances to man and animals, in order to avoid adverse effects on health. Quite simply spoken, a substance is called a poison when it can produce harmful effects in an organism. However, it should be always kept in mind that solely the dose of a substance determines whether damage occurs or not. The physician Paracelsus recognized already in the 16th century that all substances are poisons and there is no nonpoison. It is only the dose that distinguishes a poison from a remedy.

A variety of methods to assess toxic effects method. Acute toxicity testing measures morbidity and mortality after a single administration and is probably the simplest method for assessing toxic effects. On the other hand, subchronic and chronic toxicity tests investigate effects caused by a long-term administration of a compound. A further classification of toxic effects can be drawn between local and systemic effects. As an example, damage by acid burns at the site of exposure is a local effect. In contrast, systemic effects involve the affection of target organs irrespective of the exposure site. Chronic exposure to benzene, as an example, can lead to damages to the bone marrow and to leukemia after dermal exposure or inhalation. Effects of compounds on the genetic material are investigated using genotoxicity tests. Reproductive toxicology studies are carried out in order to detect effects on fertility and early embryonic development, on prenatal and postnatal toxicity, and on embryogenesis and fetogenesis. The capability of chemical compounds to induce tumors is usually examined in long-term carcinogenesis bioassays in rats and mice. Furthermore, a variety of study types to examine other end points (e.g., skin and eye irritation, skin sensitization, local injection tolerance, immunotoxicity and neurotoxicity) exist.

Although the main study types including those without statistical evaluation are summarized below in order to cover the whole spectrum, the description of the statistical analysis is mainly focused on subchronic and chronic toxicity studies. However, these methods can also be applied to other studies, if data requirements are met.

REGULATORY REQUIREMENTS

Drugs, agricultural products, and industrial chemicals must be characterized regarding safety before getting marketing authorization. With respect to this, toxicological studies are routinely required by regulatory agencies and must be conducted according to standard study protocols, which are published as so-called “guidelines” by the respective regulatory agencies. As an example, the outlines of toxicological studies needed for new drugs were evaluated by the International Conference on Harmonization (ICH). These ICH guidelines represent the European Union, Japan, and the United States, and are implemented at the national level by adopting or publishing. Regulatory requirements before an investigational new drug can be applied to humans usually include: acute toxicity testing in two species (usually rats and mice) via two administration routes, of which one should represent the intended clinical route; safety pharmacology studies covering central nervous system, cardiovascular, and respiratory end points; a minimum of three genotoxicity tests (usually Ames test, chromosomal aberration study in vitro, micronucleus test); and repeated dose studies (at least 14 days) in one rodent species and nonrodent species. The duration of the latter studies should be at least equal to the duration of the clinical trial. Generally, the route of administration should mimic the intended clinical route. Additional testing for local injection tolerance is necessary in case of parenteral administration. For a New Drug Application (NDA)

submission, additional studies investigating the effects of the drug on reproduction, on the developing fetus (usually rats and rabbits), and on prenatal and postnatal development are required, as well as chronic toxicity (6-month rodent study and 6- to 12-month nonrodent study) and carcinogenicity studies in two species (usually rats and mice). In case of industrial chemicals and agricultural products, toxicity testing requirements are similar to those applying to new drugs and are covered by the guidelines published by the U.S. Environmental Protection Agency.

STUDY DESIGN AND AIM OF STUDIES

A large number of study types were published for a variety of end points. A comprehensive description of all these study types is beyond the scope of the present paper. Therefore the following sections focus mainly on studies that are routinely applied during the safety assessment of new drugs, agrochemicals, and industrial chemicals.

Acute Toxicity

Single-Dose Toxicity

One of the first steps in studying the toxic effects of an unknown substance is the determination of its toxicity after a single administration. This provides a first indication of the kind of toxic effects and gives information about the lethal dose. In this study, the test compound is administered usually by oral, dermal, inhalational, intravenous, or other routes of exposure. The route of administration is dependent on the intended clinical use in case of drugs, or the possible route of exposure in case of agrochemicals and industrial chemicals. After administration, the animals are observed at least once daily for mortality and clinical signs of intoxication, including—but not limited to—changes in skin and fur, mucous membranes, behavior, sensory reflexes, motor activity, breathing, circulatory effects, and central nervous effects. Body weight is recorded at the start of the study and then weekly thereafter. After death or at the end of the study (usually 14 days after administration), the animals are necropsied and checked for macroscopically visible changes. In the classic test design, different dosages are selected in order to determine the LD_{50} (median lethal dose). This value describes the dose that would kill 50% of the test animals and is calculated by Probit analysis.^[1] A prerequisite for this calculation is that at least two mortality ratios are between 0% and 100%. For agricultural products and industrial chemicals, the LD_{50} value is used for the classification of compounds. However, this classic test can be replaced by the determination of the approximate LD_{50} in many cases, which saves a substantial number of test animals. Nowadays, the determination of an exact LD_{50} value is no longer needed for the approval of new drugs,^[2] agrochemicals, and industrial chemicals.^[3–6]

Testing for Acute Dermal Irritation

These tests are conducted in order to evaluate the irritant and/or corrosive effects of a compound to the skin of mammals. Whereas dermal irritation is a reversible inflammation of the skin, dermal corrosion is an irreversible damage resulting in scar formation. Usually, this test is conducted for industrial chemicals, agrochemicals, and pharmaceuticals used for dermal application.

In the skin irritation test, 0.5 g or 0.5 mL of the test compound is applied at three sites to the shaved skin on the back of one albino rabbit and covered with a semioclusive dressing. The patches are removed successively after 3 min, 1 hr, and 4 hr, and remnants of the test compound are gently removed. If no corrosive effect occurs after 4 hr, then two animals are added with one patch and an exposure period of 4 hr. If corrosive effects are observed after 3 min or 1 hr of exposure, no further testing is required. The treated skin surface is evaluated 30–60 min, 24 hr, 48 hr, and 72 hr after the removal of the patch for erythema and eschar formation as well as for edema formation. Dermal irritation is scored according to gradings of 0 (*no irritation*) to 4 (*severe irritation*). The observation period is prolonged in order to evaluate reversibility if changes are still present after 72 hr.^[7] Depending on the irritation scores, the compound is classified as nonirritant, irritant, or corrosive, if the skin is destroyed through its whole thickness.

Testing for Acute Eye Irritation

Noncorrosive substances are tested for irritant effects on the eye or mucous membranes. In this study, 100 mg (solids) or 0.1 mL (liquids) of the test substance is applied to the conjunctival sac of albino rabbits. A single animal can be used initially if a severe irritant effect is expected. In other cases, at least three animals are required. The compound is removed by rinsing the eyes 24 hr later with physiological saline. The eyes are observed 1, 24, 48, and 72 hr after application, and corneal opacity, inflammation of the iris, conjunctival irritation, and conjunctival swelling are scored according to defined gradings. The compound is then classified according to these scores. If irritation occurs after 24 hr of exposure, it may be appropriate to test additional animals with a washout 30 sec after instillation.^[8]

A number of alternative test systems have been developed to replace test systems for dermal and eye irritation due to animal welfare reasons. They can be used as a screening test for different formulations, or may replace the standard test if corrosive effects are shown.

Test for Skin Sensitization

Skin sensitization studies are carried out in guinea pigs for the determination of an allergic potential (contact

dermatitis). Several study protocols have been developed for this purpose, which in common cover the induction phase, the resting period, and the challenge period. Some of these tests include the use of Freund's complete adjuvant (FCA) for the enhancement of the immunologic process. The guinea pig maximization test of Magnusson and Kligman,^[9] which uses adjuvants, and the Buehler test,^[10] which does not use adjuvants, are considered to be preferable. During the induction period, a slightly irritant concentration of the test compound is applied by dermal or intradermal route for a possible stimulation of immune-competent cells. During the subsequent 2-week resting period, a potential antibody formation reaches a maximum. During the challenge period, the test compound is then applied as a patch to the skin in a concentration that has been shown to be a nonirritant in preliminary tests. In case of sensitization, the immunological reaction leads to erythema and/or edema formation, which should be absent in a control group induced with the vehicle only but challenged identical to the test group. The skin is examined 24 and 48 hr after removal of the patch, and erythema and edema formation are scored using a grading system. In case of the Buehler test, usually 20 animals in the treatment group and 10 animals in the control group are used. In case of the maximization test, usually 10 animals in the treatment group and 5 animals in the control group are used. However, in case of questionable results, further animals are added in this test, yielding 20 treatment animals and 10 control animals.^[11]

Depending on the animal model used, the compound is regarded as a skin sensitizer if at least 15% (tests without the use of FCA) or 30% (tests with the use of FCA) of the animals show a positive skin reaction.

Screening tests have been developed for the detection of skin sensitizers, the local lymph node assay,^[12] and the mouse ear swelling test.^[13] In case of positive results in these tests, a compound can be classified as a sensitizer without further testing.

Safety Pharmacology Studies

Safety pharmacology studies are conducted usually preclinically with new drugs in order to examine the possible adverse effects of test substances on physiological functions at therapeutic dosages and above, which could impact human safety. In vivo, ex vivo, and in vitro studies can be used. In vivo or ex vivo studies are usually carried out after a single administration of the test compound. The route of administration should be the expected clinical route. Usually three dosages are tested, of which the dose levels should equal the pharmacologically active dose and the high dose should exceed the therapeutic range by a factor of 30–100 or be the maximum tolerated dose. The central nervous system, the cardiovascular system, and the respiratory system are examined in a first step. If safety concerns arise from these studies or during later clinical

development, then supplemental safety pharmacology studies are needed.^[14]

Testing for effects on the central nervous system include behavioral tests, motor activity, coordination, and body temperature sensory and motor reflex responses, and can be measured in rats or mice according to modified Irwin's test^[15] or by using a functional observation battery.^[16]

Effects on the respiratory system should be assessed quantitatively and include measurements of respiratory rate and other respiratory parameters (e.g., tidal volume, minute volume, inspiratory time, expiratory time), which can, for example, be done in rats or guinea pigs using whole body plethysmography.

Cardiovascular function is examined by measuring blood pressure, heart rate, and the quantitative evaluation of electrocardiograms (e.g., PR, QT, QTc). Usually these tests are carried out with unanesthetized dogs instrumented for telemetric measurements. Effects of test compounds on resting potential, repolarization, and conduction abnormalities can be examined electrophysiologically in vitro using Purkinje fibers of isolated hearts, for example.

Subchronic and Chronic Toxicity Studies

These study designs are used to investigate the toxic effects of the test substance after repeated daily administration. The duration of the study ranges from 14–28 days up to 12 months. In case of drugs, the study duration depends on the intended period of therapeutic use in humans. The route of administration should reflect on the expected exposure or clinical use in humans. Usually three different dosage groups and one control group, which is handled identical to the dosage groups and receives the vehicle only, are used. The lowest dose should not cause any adverse effects, whereas the high dose should produce toxicity but no mortality or severe suffering of the animals and usually does not need to exceed 1000 mg/kg body weight (limit dose). Besides the main groups sacrificed after the end of the treatment period, additional animal groups that are allowed a treatment-free recovery period postdosing may be added in order to determine reversibility or nonreversibility of effects seen at the end of the treatment period. The animals are observed daily for health condition and at least twice daily for morbidity and mortality. Ophthalmological examinations are performed before the start and toward the end of the study. Body weight gain and food consumption are recorded at regular intervals. In case of industrial chemicals and agrochemicals, a neurotoxicological assessment is performed including sensory reactivity, grip strength, and motor activity. At the end of the treatment and recovery period, hematological and clinical chemistry examinations are carried out (e.g., erythrocyte counts, leukocyte counts, thrombocyte counts, hemoglobin, hematocrit, blood coagulation, differential blood count, electrolytes, marker enzymes, urea, creatinine, glucose, cholesterol, lipids, electrophoresis, urinalysis).

At necropsy, all animals are examined for macroscopically visible changes, the main organs are weighed, and many organs are processed for histopathological examination. In studies with a 13-week or longer administration period, additional time points or animal groups may be added in order to examine the time course and the reversibility of observed effects. The required number of animals depends on the study duration and ranges from 5 to 20 animals per group and sex in rodents. In case of subchronic and chronic studies in nonrodents (usually dogs), which are required for the registration of new drugs and agrochemicals, usually four animals per sex and group are used. Further details on subchronic studies are given in the respective guidelines (e.g., Refs. [17–20]).

The aim of these studies is to evaluate the toxicological profile of the test compound [i.e., determination of target organs, dose–response relationships, and the ‘No Observed Effect Level’ (NOEL) at which no adverse effects are encountered after repeated administration of the compound]. The NOEL is used for the extrapolation of the effects seen in animals to humans. The classic procedure uses an uncertainty factor of 10 to extrapolate from the NOEL of the most sensitive animal species to humans, and a further uncertain factor of 10 for the variability between humans. Nowadays, extrapolation is based on the corresponding plasma levels of the test compound in this species at the NOEL, and the expected plasma levels in humans, if known.

Carcinogenicity Studies

These studies are conducted in order to evaluate a possible tumorigenic action of the test compound and are described in detail in the article *Carcinogenicity Studies of Pharmaceuticals*.

Genotoxicity Studies

Heritable changes of the genetic information stored in the DNA are called mutations. On one hand, mutations are the prerequisite for the evolution process and its mechanisms such as recombination, genetic drift, or selection. On the other hand, mutations are generally random and result in deleterious effects in most cases. Therefore the aim of mutagenicity tests is to detect interactions of the test compound with the genetic material. Three principle types of mutations can be distinguished: gene mutations, chromosome mutations, and genome mutations. Gene mutations are not visible with the aid of light microscopy. One example is a change in a biochemical function, which can be induced either by a substitution of a base pair in the DNA (substitution mutation), or by a deletion/insertion of a base pair in the DNA (frameshift mutation). Changes in the structure of the chromosomes are defined as chromosome mutations and can be detected by light microscopic

techniques. They cover gaps (parts of the chromosomes that are not stained), breaks (dislocated parts of the chromatids), missing parts (deletions), or exchanges between different chromosomes. Changes in the number of chromosomes are defined as genome mutations. Like chromosome mutations, they can be detected using light microscopy. Many different test protocols for the detection of mutagens have been published, but only few are used for regulatory purposes. In principle, these tests can be divided into tests for detecting gene mutations, methods for detecting chromosome aberrations, and DNA indicator tests for identifying nonspecific interactions of the test compound with the genetic material. Selected genotoxicity assays representing these three categories are described below.

Methods for Detection of Gene Mutations

Ames assay The Ames assay^[21] uses defect mutants of the bacteria strain *Salmonella typhimurium*. In contrast to the wild type, these strains are no longer able to synthesize the amino acid histidine and therefore cannot grow into colonies in agar medium without histidine. However, this defect mutation can be reverted by mutagenic agents, and growth without histidine is enabled. The *Salmonella* strains most commonly used are TA 98, TA 100, TA 1535, TA 1537, and TA 102, which carry either substitution or frameshift mutation markers. A compound, which induces reverse mutations in this system, is detected by a concentration-dependent increase in the number of colonies. Because bacteria have only a limited capacity to metabolize xenobiotics, a fraction of rat liver homogenate (S9mix) is added in order to enable metabolism processes present in mammalian organisms. It should be kept in mind that the results of this bacterial test may have only limited relevance for mammalian systems. However, the Ames test is an easy and quick test for the detection of mutagens, and the results have a high predictability.^[22] A detailed information on the conduction of the Ames test is given in the respective guidelines (e.g., Ref. [23]).

Other test systems Test systems using mammalian cells in vitro are closer to the target species than the Ames test. Assays commonly used are the HGPRT test^[24] and the mouse lymphoma test.^[25] An important difference in bacterial systems is that, in general, two copies of each gene are present in a normal mammalian cell. Therefore mutations are studied using hemizygous or heterozygous cells. An example for a hemizygous gene (X chromosomal) is the gene coding for the enzyme hypoxanthine-guanine phosphoribosyltransferase (HGPRT or HPRT). The function of this enzyme is to salvage the degradation products of purine metabolism. However, this pathway is not essential for survival because the synthesis of purine bases can also take place de novo. Toxic purine analogues such as thioguanine and azaguanine are incorporated into DNA or RNA

in cells containing HGPRT, resulting in the death of these cells. Mutant cells with altered or absent HGPRT function are able to survive and to grow into colonies because purine bases are synthesized de novo and toxic analogues are not incorporated. Thus the principle of the HGPRT test is to detect mutagens by an increase in the number of thioguanine-resistant or azaguanine-resistant colonies after an exposure of the cells to the test compound. Because cultured cells possess only a limited metabolic capability, an exogenous metabolizing system is added. This may be done either by the addition of S9 mix, or by a coculture with metabolically competent cells (e.g., hepatocytes).

In the mouse lymphoma test cells, heterozygous cells with one active allele of the gene coding for the enzyme thymidine kinase (TK + / -) are used. This enzyme incorporates thymidine into DNA. Toxic pyrimidine base analogues such as trifluorothymidine or bromodesoxyuridine are incorporated into DNA or RNA in cells containing at least one active allele of TK, resulting in the death of these cells. Like in the HGPRT test, mutagens are detected by an increase in the number of trifluoromethylthymidine-resistant or bromodesoxyuridine-resistant colonies after the incubation of the cells with the test substance. A detailed information on the conduction of these assays is given in the respective guidelines (e.g., Ref. [26]).

Tests for Detection of Chromosome Aberrations

Chromosomal aberration test in vitro Cytogenetic tests in vitro using mammalian cell cultures are usually performed with CHO cells (ovary cells), V79 cells (fibroblasts), or human lymphocytes. The cells are incubated for a period of 3 or 24 hr with different concentrations of the test compound. After incubation, mitosis is arrested in the metaphase with Colcemid® or Colchicine. Analogous to other in vitro systems, possible metabolism can be simulated by the addition of S9 mix to the test compound. From each concentration including the control cells, at least 100 metaphase plates are evaluated microscopically for structural chromosome changes. The data are usually presented as aberrant metaphases with and without gaps and metaphases with exchanges. A compound is considered clastogenic (i.e., inducing chromosome aberrations) if a concentration-dependent or a statistically significant increase in the number of metaphases with aberrations (excluding metaphases showing only gaps) is observed. A detailed information on the conduction of this assay is given in the respective guidelines (e.g., Ref. [27]).

Chromosomal aberration test in vivo Cytogenetic tests in vivo were performed in Chinese hamsters in the past because these species has a set of only 22 chromosomes, which can be distinguished easily. However, nowadays, this species is no longer used and cytogenetic examinations in vivo are usually performed in rats or mice. The test

compound is administered to the animals twice at an interval of 24 hr at least in three doses, of which the highest one should be the maximum tolerated one. Twenty hours after the last dose, mitosis is arrested in the metaphase and the animals are killed 4 hr later. Metaphase plates of the bone marrow are examined microscopically for structural abnormalities. A compound is considered clastogenic if a dose-dependent or a statistically significant increase in the number of metaphases with aberrations (excluding metaphases showing only gaps) is observed. A detailed information on the conduction of this assay is given in the respective guidelines (e.g., Ref. [28]).

Micronucleus test The micronucleus test is used for the detection of chromosome aberrations or the interference of the test compound with the mitotic spindle apparatus. Micronuclei are DNA fragments or whole chromosomes that are not separated correctly into the daughter cells during mitosis. They can be easily detected in erythrocytes because the nucleus of these cells is expelled during maturation. Originally, this test was developed using mice, but it can also performed in rats. Groups of five male and female animals receive the test compound twice within an interval of 24 hr in usually three different dosages. After 24 hr, the animals are necropsied and bone marrow smears are taken of the femora. The incidence of micronuclei in polychromatic erythrocytes is determined in the control and dose groups. A compound is considered clastogenic in this test system if a dose-dependent or statistically significant increase in the incidence of micronuclei is observed. A detailed information on the conduction of this assay is given in the respective guidelines (e.g., Ref. [29]).

DNA Indicator Tests

Besides the test systems described above covering specific end points of mutagenesis, a number of test systems have been established for which such a clear assignment cannot be given. The results of these studies give solely a hint of a general interaction with the genetic material. One test of this class is the test for induction of unscheduled DNA synthesis (UDS test).

UDS test The UDS test measures the repair of DNA damage induced by the test compound. This test is usually performed in hepatocytes either in vitro or ex vivo. In the former case, hepatocytes are incubated with the test compound, whereas hepatocytes from treated animals are used in the latter case. DNA synthesis (incorporation of [³H]thymidine) is measured in cells, which are arrested in the G phase of the cell cycle either by autoradiography or by liquid scintillation counting of the DNA. This (unscheduled) DNA synthesis is considered to reflect repair synthesis due to previous DNA damage. A detailed information

on the conduction of this assay is given in the respective guidelines (e.g., Ref. [30]).

Reproductive Toxicity Studies

Reproductive toxicity studies are conducted in order to evaluate effects to any stage of the reproductive cycle and are described in detail in the article *Reproductive/Development Studies*.

AIMS AND ISSUES IN STATISTICAL ANALYSIS

The following sections mainly deal with the statistical analysis of continuous parameters in subchronic and chronic toxicity studies. Nevertheless, some of the statistical techniques and tests presented below could easily be adapted to other study types, depending on the kind of data and study design to be analyzed. Only a few hints and additional literature for the analysis of some study types mentioned above will be given now. The statistical analysis of the Ames assay, including its specific statistical problems (i.e., the high variability of the data and the overlapping toxic and mutagenic effects at higher dose levels), has been described, for example, by Schumacher and Schmoor^[31] or by Hoffmann.^[32] A proposal for a statistical analysis for the HGPRT assay was given by, for example, Liu and Chow.^[33] To analyze the outcome of a micronucleus test statistically, a pairwise one-sided exact Wilcoxon test (see also “Statistical Approaches”) could be used in order to compare the incidence of micronuclei of the treated animals with the control. Another approach based on the Fisher–Pitman permutation test has been established by Leimer et al.^[34]

Aim of the Analysis

The main scope of statistical analysis for a toxicological study is to support the interpretation of the study outcome. In a typical subchronic or chronic toxicity study, around 50 parameters of hematology, clinical chemistry, urinalysis, and organ weights are under investigation, sometimes measured twice or even more during the course of the study. In addition, body weight and food consumption often are measured weekly. Due to this high amount of parameters and measurement times in most types of studies, it is hardly feasible to get one statistical decision on a predefined significance level for a complete study, which reflects the aim of the studies in most cases better, to make several statistical decisions on a studywise multiple significance level. In order to support the interpretation of the study results according to the aim of the studies (i.e., identification of the NOEL), one has to take into account that, on one hand, enough power is available to find toxicological relevant effects and, on the other hand, the studywise significance level should still be under control, if feasible. Using tests on differences, which is still the

commonly accepted method in toxicology, the aspect of an adequate power is most important as also discussed in following sections. Therefore it has been widely agreed to implement a multiple significance level of 5% for each parameter, measurement time, and sex, and not try to achieve a more comprising multiple significance level. Nevertheless, sometimes, still more than 100 statistical decisions have to be made, each of them on a 5% significance level. Discussions around this issue can be found in Hothorn.^[35]

How could statistical results gathered in that way be interpreted adequately? In general, the study director himself makes the final decision about toxicological effects. Either the study director accepts some minor toxicological effects—if any has been found at all—or the study director concludes to reject the substance. Depending on the study director’s knowledge about statistics, and attitude toward statistics, the statistical test results are used in a more or less descriptive way in most cases, especially when using routine analyzing systems without the involvement of statisticians. In very simple terms, the number of significances weighted by the importance of the parameters under investigation, combined with some general impressions based on the study data, leads to a general judgment about the substance under investigation. In addition, individual test outcomes on each parameter help to identify possible toxic end points. Only in some rare cases, especially when critical decisions have to be made, do statisticians have to be involved for a deeper analysis to support the interpretation of the results. In all other cases, the final decision is still made based on a high amount of experience of the toxicologist. Therefore it must be the aim of statistical analysis to influence this decision by adequate, objective inferential statistical methods. This should lead to more objective conclusions on the outcome of studies.

Equivalence Tests—The Better Choice?

Because it is the aim of toxicological studies to find a dose level where no relevant effect of the substance under investigation is present (NOEL), the use of statistical tests on differences between a treatment group and a control group seems to be questionable. Only if the results of these tests show no significant difference for a dose group under investigation is it concluded that no relevant effect occurred. However, it has to be emphasized that the probability for a wrong decision—the so-called β error, or error of the second kind—in this case is unknown. Therefore the power of the tests, defined as $1 - \beta$, is also not under control. However, because these tests are still in common use, the following sections rely on them and describe how to use them in a proper manner, which is definitely not optimal due to the above described property. Only a short introduction in equivalence tests, which would fit much better to make safety assessments, restricted to the two-sided case is given now.

The null hypothesis H_0 of an equivalence test is formulated as a two-sided difference and the alternative H_A is formulated as an equivalence hypothesis:

$$\begin{aligned} H_0: x_T &\geq x_0 + \delta \text{ or } x_T \leq x_0 - \delta \\ H_A: x_0 - \delta &< x_T < x_0 + \delta \end{aligned}$$

where x_0 is the mean of the control group; x_T is the mean of the treatment group; and δ is the limit of relevance region.

The main issue of an equivalence test is the a priori determination of the relevance region by a definition of the relevance limit δ . Although the a posteriori definition of δ has been described in Hauschke and Hothorn,^[36] an a priori definition should be preferred because it leads, in general, to more objective test results not affected by the outcome of the study itself. Once a suitable relevance limit has been found, it can be seen that there are two advantages of equivalence tests compared to tests on differences. First, as already described, the probability of erroneously deciding for equivalence—and therefore no toxicological effect—is fixed now. It is the error of the first kind or significance limit α that has to be a priori defined in the study protocol. Second, it is possible now, by defining δ correspondingly, to include a relevance of the statistical decision instead of only relying on the absence of a statistical significance while testing on differences.

In toxicological studies, a general issue for the a priori definition of the relevance limit δ is the high amount of parameters. Individual definitions of δ for each parameter based on the experience or knowledge of the study director about an adequate level of relevance would be highly influenced by a subjective opinion of toxicologists. A more objective approach for the determination of an adequate relevance limit δ could be based on a rule, which fits for all parameters and takes into account the estimated standard deviation of control animals based on historical data. Wellek^[37] describes an approach to use 75% of the standard deviation for normally distributed data, if no a priori definition of the relevance limit could be achieved, but not in the context of toxicological studies. Therefore some more experience has to be gained before using this method. It has to be discussed in detail if, on one hand, a general approach for all parameters is feasible and if, on the other hand, 75% of the estimated standard deviation based on historical controls could be accepted by toxicologists as a reasonable value for the definition of toxicological equivalence.

Some aspects of the practical use of equivalence tests (e.g., the description of the one-sided test problem and two-sided test problem, the determination of the NOEL under the assumption of a monotone dose–response relationship, and the use of parametric and nonparametric tests) have been described in Hauschke and Hothorn.^[36] However, due to the still existing issue in determining δ , further discussions within this paper only refer to the

assumption that tests on differences are used to analyze toxicological data.

Statistical Significance Vs. Toxicological Relevance

When using tests on differences, a general question arises by the discussion about the relevance of statistical significances. The power of a statistical test to find an existing difference between treatment groups and control is the essential criterion for the quality of a test on differences. It depends on the actual difference, the sample size, the variance of the underlying distribution, and the predefined α level. Most toxicological studies are planned based on recommendations of guidelines especially as far as the sample size is concerned. Also, a significance level of 5% is in common use. Therefore the power to find an existing difference may vary for each parameter within a study, as the variance of the underlying distribution could be different. This may lead to situations where even small differences in means between treatment and control could result in significant findings, which may not be relevant from a toxicological point of view. On the contrary, relevant effects might not be significant due to a low test power. As long as tests on differences are in use, this major disadvantage has to be taken into account while interpreting significances. It has to be pointed out that the power of a test cannot be determined a posteriori based on study data because the true difference in treatment and control means and the true variances of the underlying distribution of the data are unknown.

Issue of Heterogeneous Variances

The variance homogeneity assumption for all groups under investigation, which is the prerequisite for parametric statistical methods, does not hold in general. Unfortunately, variances could be affected by treatment (e.g., increasing dose levels could not only affect the mean values but could also lead to increasing variances). Other variance structures would also be conceivable but seem to occur rather exceptionally in toxicology. Some parametric statistical tests have been described in the literature, which are able to adjust for heterogeneous variances. The Welch *t*-test as a pairwise comparison seems to be well approved (a description could be found in a section below). In the field of trend tests, two examples should be mentioned here: the Welch trend test and the robust contrast-based trend test proposed by Meng et al.^[38] Both tests are described in Bailey.^[39] Some further investigations on the behavior of the robust contrast-based trend test performed by the University of Applied Sciences in Darmstadt^[40] showed two major disadvantages that lead us to the conclusion not to use or to recommend it in toxicological studies. First, for given mean values depending on the variance structure of the control and treatment groups, the power of the test could range from about 20% up to 90%, as presented in the original paper. This extreme variation in

the power is hardly acceptable in toxicology because it is an important quality criterion for a test on differences. Second, depending on the number of groups under investigation and on the sample size balance of the groups, the influence of groups is reduced or even eliminated. For example, in the case of three groups with equal sample sizes, only groups 1 and 3 are taken into account for the calculation of the test statistic. Therefore essentially a pairwise comparison is performed and no trend alternative is tested. This varying behavior of the test, depending on the variance structure and even the number of the groups under investigation, is also not desirable.

The Welch trend test is also described in Bailey,^[39] who points out that the amalgamation procedure for the adaptation of group means to bring them in a nondecreasing order used in this test could lead to misleading test results. Therefore this test seems also not suitable for the routine use in toxicology.

For nonparametric methods in general, although the assumption of same distributions, which includes equal variances, should be kept, these methods are robust against violations of variance homogeneity. The reason seems to be the transformation of the original data into ranks, which are obviously only affected by changes in variances between groups if these changes lead to different rank orders of the original values.

In summary, one can say that the issue of variance heterogeneity is well examined and could be taken into account in the case of parametric pairwise comparison procedures and also for nonparametric procedures. Some investigative work still has to be done if parametric trend tests should be established.

STATISTICAL APPROACHES

As already described, a 5% significance level per parameter, sex, and measurement time is recommended for the analysis of toxicological studies and, as long as tests on differences are used, the power of the methods is essential. Therefore it is important for the analysis to increase the power as much as possible in order to decrease the false-negative error rate (i.e., ensuring that existing toxicological effects lead to statistical significances with a high probability, and therefore minimizing the consumer's risk). First of all, several statistical techniques are described in the following sections, which are useful to achieve this aim, given the standard toxicological study designs described above. A discussion of some useful tests on differences follows. It is not intended to present a complete list of possible tests but a useful subset of established methods for toxicology. Other tests could also be used in combination with the presented statistical techniques, if adequate. A general step-down procedure is described; pooling control groups, the use of one-sided tests, parametric vs. nonparametric testing, the use of trend tests vs. pairwise testing,

and baseline corrected values are discussed as possible statistical techniques to increase the power. All of them may be used for the parameters under investigation either in combination with each other or a subset of them as long as the assumptions for an individual parameter are fulfilled and also accepted by the responsible study directors. However, for the correctness of the methods described below, it is required that a suitable randomization procedure has been performed to assign animals to study groups.

Other approaches will not be mentioned here. The decision tree approach especially, often used in former times, is not recommended for toxicology. Bailey^[39] discussed the disadvantages of this method.

Techniques to Improve Power of the Analysis

Multiple Comparison Procedures

Based on the above described study designs, the statistical inference could be viewed as an analysis of variance (ANOVA) problem. Due to the described aim of the studies, many-to-one comparisons of treatment groups with the control within the ANOVA model, either based on pairwise tests or trend tests, is adequate. In study types, where increasing doses of a substance are under investigation, usually the dose-response relationship is monotone, although there are exceptions from this rule. If this assumption was not verified or could not be accepted a priori for a toxicological study, it would not be possible to identify a NOEL as described in the sections above. For general situations, where this assumption does not hold, pairwise testing of the treatment groups vs. the control is recommended with an additional correction of the p values per parameter, sex, and measurement time based on the procedure of Holm^[41] in order to keep to a multiple significance level of 5%. One special situation, which could, for example, occur in the analysis of mutagenicity testing, is the so-called rainbow alternatives. At low doses, there is an increase in the response, but at high doses, there is a decrease. Schmoor and Schumacher^[42] have discussed some adaptive procedures to handle these situations. In a first step, a range is estimated, where the response seems to be increasing. The highest dose groups not belonging to this range are eliminated and then, for example, a trend test could be performed based on the remaining groups.

If a monotone dose-response relationship is confirmed, the following statistical method for identification of a NOEL, at least restricted to the parameter under investigation, is reasonable. It is a step-down procedure for general use, which is very easy to implement and could be used for all pairwise and trend tests described below. It has been established by Hothorn and Lehmacher:^[43]

1. Test for the highest dose group vs. control, or trend test for all groups on a significance level of α .
2. If significance is found, eliminate the highest dose group and go back to step 1 with the remaining

groups. If no dose groups are left, stop the procedure; no NOEL could be identified. If no significance is found, go on with step 3.

3. The highest dose group of the remaining groups is identified as the NOEL. Lower dose groups are expected to show no relevant difference to control.

Hothorn and Lehmacher showed that this procedure is based on the closed testing principle and keeps to a multiple significance level of α . In the case of a monotone dose–response relationship, the power of this procedure is much better than the more general Holm procedure due to the use of an uncorrected α for each individual test.

Trend Test Vs. Pairwise Comparisons

Also based on the assumption of a monotone dose–response relationship, the use of trend tests is justified. In comparison to corresponding pairwise comparisons of each treatment group with the control, trend tests are in general more powerful due to the use of more information, which is given by the groups between the control and the highest dose group. Nevertheless, one has to take into account that limitations are given in the parametric case, if variance homogeneity cannot be assumed as already pointed out. Either parametric trend tests not adjusting for heterogeneity could be used, relying on their robustness, or pairwise comparisons (e.g., Welch *t*-test) accepting the lower power could be used.

Pooling Control Groups

In order to increase the power of a statistical test for some parameters, it is feasible to pool male and female animals. The decision about pooling could either be based on the experience of toxicologists, that no difference between both sexes exists, or based on investigations of historical control data. However, pooling is only adequate for control groups because it cannot be foreseen if a substance under investigation affects both sexes in the same way or not. Therefore a separate analysis should be done for males and females, but the same common control group could be used for both comparisons.

One-Sided Testing vs. Two-Sided Testing

A toxicological effect on a parameter either leads to an increase or a decrease of the values of treatment groups in comparison to a control. In most cases, the direction a priori is not known. Therefore two-sided testing is adequate in general. If a step-down testing procedure is used (see the section “Multiple Comparison Procedures”), the test direction could be determined on the test of the highest dose group. Therefore due to the assumption of a monotone dose–response relationship, one could easily change to one-sided tests based on the predetermined test direction

for all following steps (i.e., for the tests of the lower dose groups). Obviously, the power of these tests is increased.

For some parameters, only either an increase or a decrease of the treatment group mean in comparison to the control is relevant in order to support toxicological questions. In these situations, it is recommended to use one-sided tests instead of the general use of two-sided tests.

Parametric Method Vs. Nonparametric Method

Parametric methods rely on the assumption of an underlying normal distribution. Although the robustness of parametric methods concerning violations of this assumption has been widely accepted, nonparametric methods are available, where the assumption of a normal distribution is not required. Only the assumptions of equal distributions for all groups and variance homogeneity have to be fulfilled—as for a lot of parametric methods also. Therefore from a theoretical point of view, nonparametric methods are a well-proofed alternative and are able to handle situations where the underlying distribution is not known or known to be not normal. Many authors have described the behavior and have recommended the use of these methods in case of uncertainty about the distribution. For example, Hollander and Wolfe^[44] emphasize that in most cases, nonparametric procedures show only a slightly less efficiency than parametric procedures in case of normality. Bailey^[39] even points out that nonparametric methods are more powerful than the equivalent parametric tests when the assumptions are not fulfilled for a parametric analysis.

Also from a practical point of view, nowadays it is adequate to use nonparametric methods. Some time ago, one had to rely on asymptotic tests due to computational issues of the exact distribution. Especially in toxicology, the use of asymptotic tests should be avoided due to the small sample sizes. During the recent decade, powerful computer algorithms have been developed and established in statistical software to enable exact and fast calculations of *p* values for nonparametric methods. Two algorithms are mentioned here because both have been in use by the authors and seem to work with a high efficiency. First, the shift algorithm developed by Streitberg and Röhmel^[45] could be implemented for most types of programming language. In addition, the network algorithm introduced by Metha and Patel^[46] could be found in the software packages StatXact and SAS (version 8.0 and higher). Both software tools provide exact *p* value calculations, for example, for the Wilcoxon and Jonckheere–Terpstra tests (see following sections).

For the presentation of results from nonparametric methods, it is recommended to show the median in addition to the mean, standard deviation, and sample size as descriptive statistics. Especially when only small sample sizes are in use, the mean value could be affected enormously by outlying values while the median is not.

Baseline Correction

Depending on the study type for some parameters, baseline values, taken right before the treatment of the animals starts, are available. In a descriptive way, sometimes these values are used to check if no undesired randomization for the assignment from animals to study groups occurred. For example, if all heavy animals have been assigned randomly to the control group, significant effects in the treatment groups (e.g., a reduced absolute food consumption) may not have occurred due to treatment. Another way to use these baseline values could be the correction of values taken under treatment or during recovery (i.e., calculation of changes to baseline). Under certain circumstances, these differences could lead to a reduction of the variance of the corrected values in comparison to the absolute values. In these cases, the power of the statistical analysis would be improved.

Body weight changes seem to be a well-established example for a baseline correction in toxicology. Obviously, only the change of the body weight is reflected without looking at the initial weight. At least under the assumption that treatment could affect animals independently of the initial body weight, all randomization issues concerning this parameter are eliminated.

For some study types, baseline values are also available for other parameters, such as hematology or clinical chemistry. Because the changes in these values are not in common use, it is not recommended to perform baseline corrections in these cases.

Statistical Tests

The scope of the next sections is the presentation of some univariate parametric and nonparametric trend and pairwise tests, which could be used in the analysis of toxicological studies. It is not intended to describe these tests in detail, but some hints on further literature are given. In addition, SAS procedures (version 8.0 and higher) to perform these tests are mentioned, if available. One assumption has to be kept for all of the following tests: The parameter values under investigation have to be stochastically independent. Therefore only one value per animal is allowed to be included in the test. Multivariate procedures would allow analyzing more than one value per animal (e.g., some time points of one parameter or some parameters in one analysis). Because these procedures are not investigated well enough in the framework of toxicological studies, only univariate procedures will be described.

Student's *t*-Test

The *t*-test is a pairwise test to identify a difference in means between two groups of parameter values. The populations of the two groups have to be normally distributed with equal variances (variance homogeneity) with regard to the parameter under investigation. In the two-sided

test, the null hypothesis “no difference in means” (i.e., the populations of both groups are equal) is tested against the alternative “existing difference in means” (i.e., populations are different with regard to the mean).

The null hypotheses of one-sided tests are constructed as follows: either the mean of group 1 is smaller than or equal to group 2, or group 1 is bigger than or equal to group 2. The alternatives of one-sided tests are formulated correspondingly: either the mean of group 1 is bigger than group 2, or vice versa.

In toxicological studies, because variances have to be equal between control and treatment groups, it would be reasonable to calculate a common variance estimation for all groups, which is a better estimation due to higher sample size, than to calculate variances for each of the two groups under investigation individually. This common variance estimation can be used in all individual tests.

A detailed description of Student's *t*-test was, for example, given by Yamane.^[47] Calculations could be done with the SAS procedure TTEST. A common variance estimation could be performed using the procedure GLM.

Welch *t*-Test

As the *t*-test described above, the Welch *t*-test is also a pairwise test to identify a difference in means between two groups of parameter values. Normal distribution is required, whereas variances are allowed to differ between the groups. In case of same variances in both groups, the Welch *t*-test is less powerful than the *t*-test. The hypotheses to be tested in the one-sided and two-sided cases are the same as described for the *t*-test.

A detailed description of the Welch *t*-test could be found, for example, in Lehmann.^[48] Calculations could be done with the SAS procedure TTEST.

Williams Test

The Williams test is a parametric trend test based on the *t*-test described above. The assumptions of the *t*-test have to be given (normal distribution and variance homogeneity) and, in addition, a monotone dose-response relationship has to be assumed. If the sample means are not in increasing or decreasing order, an amalgamation procedure is performed first, recalculating the means to correct the order. In some rare cases, this procedure leads to the same results for a data set using one-sided tests in both directions. This has to be taken into account while interpreting the test results.

In the two-sided case, the null hypothesis “no difference in means” is tested against the following alternative:

Either monotone-increasing means with the mean of the highest dose group is bigger than the mean of the control, or monotone-decreasing means with the mean of the highest dose group is smaller than mean of the control.

One-sided alternatives are constructed straightforwardly using only the corresponding part of the two-sided alternative.

The Williams test including the amalgamation procedure is well described in Bailey.^[39] Critical values for this test, which are important for implementation, are given in the original publications by Williams.^[49,50]

Linear Contrasts Within an ANOVA

Linear contrasts within an ANOVA can be used for a test on a linear trend. The populations of the groups under investigation have to be normally distributed with equal variances. Only one-sided linear trend alternatives can be tested with linear contrasts. Some useful contrasts for testing other alternatives have been presented by Bailey.^[39] Computation considerations could be found, for example, in Neter et al.^[51] The SAS procedure GLM can be used to calculate tests based on linear contrasts.

Unfortunately, sometimes it is recommended to perform a standard ANOVA first—testing the null hypothesis of no differences between any group under investigation against the alternative of at least one group being different from the others without taking into account the monotone dose–response relationship. Only when a significance is found in this overall test are additional contrasts calculated to identify the NOEL. It has to be taken into account that the overall test is less powerful than a linear contrast for all groups under investigation, because it does not consider the assumption of a monotone dose–response relationship. Instead, a very general alternative is tested. Therefore it is more reasonable to avoid this overall test.

ANOVA with Rank Transformations

An easy method to perform nonparametric tests using the same linear contrasts in an ANOVA model as described above could be implemented by rank-transforming the data first (i.e., sorting data values in increasing order, assigning ranks to all data values, and using these ranks for the following analysis), which can be performed as described above. This procedure has been presented by Conover and Iman.^[52] The rank transformation could easily be done by the SAS procedure RANK in the following analysis as described in “Linear Contrasts Within an ANOVA.”

Wilcoxon Test

The Wilcoxon test is a nonparametric test to perform pairwise comparisons between two groups. The calculation of the test statistic is based on the ranks of the parameter values. The same continuous distributions in both groups are required; differences in the means of the underlying distributions can be identified. Nevertheless, also discrete data can be analyzed if the number of ties is not too big.

The hypotheses in the one-sided and two-sided cases are the same as for the *t*-test.

It is recommended to calculate exact *p*-values (see the section “Parametric Method vs. Nonparametric Method”) when using this test in toxicological studies due to the small sample sizes.

Hollander and Wolfe^[44] described the Wilcoxon test in detail. The exact *p* values could be calculated with the SAS procedure NPAR1WAY.

Jonckheere–Terpstra Test

The Jonckheere–Terpstra test is a nonparametric trend test to identify monotone-increasing or monotone-decreasing trends of the parameter under investigation with regard to the increasing dose levels. The distributional assumptions are the same as for the Wilcoxon test. The hypotheses to be tested in the one-sided and two-sided cases can be found in “Williams Test.”

As with the Wilcoxon test, exact *p*-values should be calculated.

A detailed description of the Jonckheere–Terpstra test could be found, for example, in Hollander and Wolfe.^[44] The SAS procedure FREQ delivers exact *p* values.

Normal Range Comparisons

Normal ranges could be used as an additional statistical instrument to discuss the relevance of test decisions, if tests on differences are used. Any statistically proofed differences between dose group and control might still be interpreted as not relevant if both groups are identified as normal according to the calculated normal ranges. Otherwise, if the dose group is proofed to be abnormal and the control is not, the relevance of the test result seems to be verified. Two major problems should be mentioned when analyzing historical data. First, in some study types, multiple measurements per animal may be taken. Therefore not all values of the historical data pool are stochastically independent. In this case, a randomized selection of one value per animal is recommended. Second, it should be taken into account that age-dependent parameters could exist. This is not relevant for short-term studies, if only animals with similar age had been used. If the age of the animals in the historical data pool varies strongly, one should think about an adequate correction of the values with regard to age.

Only one method to calculate normal ranges, able to classify a complete group of animals as normal or abnormal, should be mentioned here. Passing et al.^[53] described a nonparametric prognose region, which could be used to calculate a normal region containing, on average, 95% of the population. A group of animals of a current study is classified as normal when at least 75% of the values lie within the corresponding range.

The basis of normal range calculations is professional data management, which has to ensure that historical data

are stored and updated correctly over a long period of time, including age, species, strain information, and other available parameters to be taken into account for the calculations.

Two Concepts for Analyzing Chronic or Subchronic Toxicity Studies

Two possible concepts for the routine analysis of hematology, clinical chemistry, and urinalysis parameters of a chronic or subchronic toxicity study will be presented here, both using some of the techniques and statistical tests presented above. Two hypothetical companies are investigated for demonstration. In addition, some recommendations are given for the analysis of body weights, organ weights, and food consumption, valid for both companies. One general rule should always be taken into account: Keep the analysis as simple as possible.

First Concept

No knowledge about the distribution of the parameters is available in the first company, where toxicological studies have never been done before. Therefore it has been decided to use a nonparametric test instead of relying on uncertain assumptions of normally distributed parameters. Because only increasing doses of one substance will be analyzed routinely and the toxicologists agreed on the assumption of a monotone dose–response relationship, a nonparametric Jonckheere–Terpstra trend test is selected for the analysis of all parameters. For special studies, where this assumption seems obviously be not valid, a statistician should be involved. Because the toxicologists in this company are inexperienced, also no knowledge is available about differences between sexes for individual parameters and relevant directions of possible toxic effects could be gathered; the decision is made by analyzing sexes separately and performing two-sided tests. A step-down procedure according to Hothorn and Lehmacher (see the section “Multiple Comparison Procedures”) is adequate, with the detection of the test direction based on all dose groups followed by one-sided test for further steps. Because no historical data are available, normal range calculation is not possible.

Second Concept

In a second company, historical data of control animals have been gathered and well managed and maintained since more than 10 years ago. In addition, toxicologists have decided to go on with the same animal strains that have been used since the beginning of toxicological studies in this company, for the future. Now, in order to define a new statistical concept, the decision is made to analyze the historical data pool. A basic question is the normal distribution assumption for the individual parameters. Even if it is expected that about 80% of the parameters could not be identified as normally distributed (according to Bailey^[39]),

toxicologists are interested in improving the power by using parametric methods for about 20% of the parameters found to be normally distributed. It has been decided to use the Williams test for normally distributed parameters and the Jonckheere–Terpstra test for others.

The toxicologists have agreed on a list of parameters, where no differences between untreated male and female animals are expected, and also a list of parameters, where one toxicologically relevant test direction has been identified. Therefore pooled control groups and one-sided tests as described above are implemented for the corresponding parameters. Normal ranges are calculated as described in the “Normal Range Comparisons” and will be used for additional information because many of the historical data are available.

Analysis of Body Weights, Organ Weights, and Food Consumption

In both companies, toxicologists confirm that body weights, absolute organ weights, and food consumption are normally distributed parameters. They also insist on the analysis of body weight changes (i.e., baseline corrected values). Because it cannot be assumed that variances of control and treatment groups are equal, and no well-working trend tests have been found in the literature, the decision is made to use a pairwise two-sided Welch-*t* test for routine analysis. In some situations, organ weights will have to be analyzed relative to final body weight or to brain weight, which is even better due to a lower intra-animal variation in contrast to body weight. In addition, food consumption should be analyzed relative to corresponding body weights. It is a fact that normally distributed parameters divided by each other are not normally distributed anymore. Therefore nonparametric methods as described in the first concept will be used in these cases.

Comparison of Concepts

The advantage of the first concept is its easy implementation and straightforward interpretation of the test results. The second concept is a more advanced combination of the statistical techniques presented above. Without a doubt, the implementation is expensive and takes some time in planning to discuss details very carefully. Once established, toxicologists have to be aware of the methods in use in order to prevent a misinterpretation of the statistical results. Nevertheless, on the average, some more significances will be found due to a higher power in some parameters.

CONCLUSION

Before starting a toxicological study, a concept for the statistical analysis has to be determined and described in a study plan. On one hand, adequate statistical tests

for toxicological parameters have to be selected; on the other hand, the general statistical techniques described above should be discussed very intensively. As long as assumptions for a statistical test are fulfilled, it is a second-rate question as to which test should be preferred for parameters, if more than one is available. A selection of possible tests has been described in the sections above to provide an overview of well-accepted methods. In order to increase the power of the statistical analysis, it is even more important to apply the above described statistical techniques, if possible. Most of them are independent of the use of a special test. However, they are powerful tools, which are able to improve the quality of a statistical analysis of toxicological parameters, if used adequately. Nevertheless, the concept for the analysis of toxicological studies has to be well discussed and accepted by statisticians and toxicologists.

Although there are still statistical areas where an improvement of the methods is necessary in order to provide a most efficient support of toxicological decisions—especially variance heterogeneity situations and multivariate analysis should be mentioned here—many achievements have already been made. The broad acceptance of nonparametric methods and multiple comparison procedures as the step-down procedure described above is one important example.

Some statistical areas are well discussed in the literature but are still not in common use. Here, it should be emphasized that especially the practical use of equivalence tests needs more investigative work. Not only the way of providing equivalence limits for a huge amount of toxicological parameters is still not well discussed and generally accepted, also the interpretation of the results is different from the common methods in use. It has to be well discussed by toxicologists and statisticians in order to get a common understanding and a broad acceptance—not only by people involved in the conduction of studies but also by the administrative persons responsible.

Traditional Chinese Medicine (TCM): Clinical Development

Fuyu Song

Duke University School of Medicine, Durham, North Carolina, U.S.A.

Abstract

In recent years, the use of complementary and alternative medicine including botanical drug products and traditional Chinese (herbal) medicine (TCM) in humans for treating critical and/or life-threatening diseases has received much attention. In pharmaceutical/clinical development of a given TCM, one of the major criticisms is lack of objectively scientific evidence (documents) of clinical safety and efficacy. Unlike the Western medicines (WMs), TCM often consists of multiple components (active ingredients) whose pharmacological activities are often unknown or are not fully characterized or understood. Thus, standard methods for WM clinical trials may not be appropriately applied directly to TCM clinical trials. In this article, some statistical considerations including selection of study design, preparation of matching placebo, development of study endpoint, validation of an instrument, calibration of the validated instrument, and power calculation for sample size estimation are discussed. These considerations have an impact on effectively and scientifically evaluation of clinical safety and efficacy of TCM in clinical trials. In addition, some practical issues regarding test for consistency in raw materials, stability of drug substance, and animal studies are also discussed.

Keywords: Botanical drug products; Calibration; Herbal medicine; Matching placebo; QOL-like instrument.

INTRODUCTION

In recent years, the search for complementary and alternative medicine such as botanical drug products and traditional Chinese (herbal) medicine (TCM) for treating critical and/or life-threatening diseases has received much attention. This has led to the study of the potential use of promising TCMs. As indicated by Chow et al.^[1] and Chow,^[2] TCM originated in ancient China has evolved over several thousands of years, which usually refers to a broad range of Chinese medicine practice including various forms of herbal medicine, acupuncture, massage (*Tui Na*), exercise (*Qi Gong*), and dietary therapy. In pharmaceutical/clinical development of a test treatment, one of the major criticisms for the development of TCM is lack of objectively scientific evidence (documents) of clinical safety and efficacy. Unlike the Western medicines (WMs), TCM often consists of multiple components (active ingredients) whose pharmacological activities are often unknown or are not fully characterized or understood. Thus, standard methods for evaluation of WM clinical trials (see, e.g., the works of Chow et al.^[1–3]) may not be appropriately applied directly to TCM clinical trials.

In TCM clinical development, it is a concern whether a TCM can be scientifically evaluated in the Western way due to some fundamental differences between a WM and a TCM. These fundamental differences include differences in formulation and drug administration, medical theory/practice, diagnostic procedure, and criteria for evaluation.^[1] As an example, the Chinese diagnostic procedure for patients with certain diseases consists of four major techniques: inspection, auscultation and olfaction, interrogation, and pulse taking and palpation (see also the work of Chow^[2]). Under these differences, it is of interest to the investigators regarding how to design and conduct a scientifically valid (i.e., an adequate and well-controlled) clinical trial for the evaluation of the clinical safety and efficacy of the TCM under investigation. In addition, it is also of particular interest to the investigators as to how to translate an observed significant difference detected by the Chinese diagnostic procedure to a clinically meaningful difference based on some well-established clinical study endpoints. The purpose of this article is not only to describe some perspectives regarding TCM development but also to provide some basic considerations regarding practical issues that are commonly encountered during the

conduct of clinical trials in the development of TCMs in the Western way. These statistical considerations include selection of study design, preparation of matching placebo, development of study endpoint, validation of an instrument, calibration of a validated instrument, and power calculation for sample size estimation.

In the next section, some perspectives regarding TCM clinical development are described. The “Basic Considerations” section provides some basic (statistical) considerations for TCM clinical trials. Some practical issues that are commonly encountered during the process of development of a TCM are reviewed in the “Practical Issues” section. Some concluding remarks are given in the last section.

PERSPECTIVES OF TCM CLINICAL DEVELOPMENT

For clinical development of TCMs, before a TCM clinical trial is conducted, the following questions are necessarily asked.

- 1. Will the TCM clinical trial be conducted by Chinese doctors alone, Western clinicians alone, Western clinicians who have some background and experience of Chinese herbal medicine alone, or both Chinese doctors and Western clinicians?
- 2. Will traditional Chinese diagnostic procedure and/or trial procedures be used throughout the TCM clinical trial?
- 3. Upon approval, is the TCM intended for use by Chinese doctors, Western clinicians, or both?

For the first two questions, if the TCM clinical trial is to be conducted by Chinese doctors alone, the following questions arise: first, should the Chinese diagnostic procedure be validated in terms of its sensitivity, specificity, and consistency (reproducibility) in order to provide an accurate and reliable assessment of the TCM? In addition, it is of interest to determine how an observed difference obtained from the Chinese diagnostic procedure can be translated to the clinical endpoint commonly used in similar WM clinical trials with the same indication. These two questions can be addressed statistically by the calibration and validation of the Chinese diagnostic procedure with respect to some well-established clinical endpoints for evaluation of WMs. If the TCM clinical trial is to be conducted by Western clinicians or Western clinicians who have some background of Chinese herbal medicine, the standards and consistency of clinical results compared to those WM clinical trials are ensured. However, the good characteristics of TCM may be lost during the process of the conduct of the TCM clinical trials. On the other hand, if the TCM clinical trial is to be conducted by both Chinese doctors and Western clinicians, differences in medical practice

and/or possible disagreement regarding the diagnosis, treatment, and evaluation are the major concerns.

For the third question, if the TCM is intended for use of Chinese doctors but it is conducted by Western clinicians, difference in perception regarding how to prescribe the TCM is of great concern. The preparation of a package insert based on the clinical data could be a major issue, not only to the sponsor but also to regulatory authorities. Similar comments apply to the situation where the TCM is intended for use of Western clinicians, but the trial is conducted by Chinese doctors.

As a result, it is suggested that the intention of use (i.e., labeling for the indication) be clearly evaluated when planning a TCM clinical trial. In other words, the sponsor needs to determine whether the TCM is intended for use of Western clinician only, Chinese doctors only, or both Western clinicians and Chinese doctors at the planning stage of a TCM clinical trial, for an adequate package insert of the target diseases under study.

BASIC CONSIDERATIONS

To effectively and scientifically evaluate the clinical safety and efficacy of a TCM under investigation, as indicated by Chow and Song^[4], a valid study design with some basic considerations for an intended clinical trial is necessarily considered for achieving study objectives with a desired power under the perspectives described in the previous section (see also the FDA guideline^[5]).

Selection of Study Design

Let WW and CW denote conducting a clinical trial the Western way (i.e., based on Western well-established clinical endpoints) and the Chinese way (i.e., based on traditional Chinese diagnostic procedures), respectively. Depending upon the study endpoints (or diagnostic procedures), clinical trials can be classified into the following four different types (see Table 1):

Type I clinical trials, denoted by WM₁₁ are classic clinical trials for WMs that utilize well-established Western clinical endpoints before and after treatment.

Type II (TCM₁₂) clinical trials usually refer to those TCM clinical trials utilizing well-established Western

Table 1 Types of WM and TCM Clinical Trials

Pretreatment (screening)	Posttreatment	
	1 (WW)	2 (CW)
1 (WW)	Type I = WM ₁₁	Type II = TCM ₁₂
2 (CW)	Type III = WM ₂₁	Type IV = TCM ₂₂

WW, Western way; CW, Chinese way; WM₁₁, utilizing WW in both pre- and post-treatment; WM₂₁, utilizing CW in the pre-treatment and WW in the post-treatment.

clinical endpoints at screening (pretreatment) and evaluating the test treatment the Chinese way (i.e., based on Chinese diagnostic/evaluating procedures) posttreatment.

Type III (WM₂₁) clinical trials usually refer to those WM clinical trials utilizing Chinese four diagnostic procedures at screening (pretreatment) and evaluating the test treatment the Western way posttreatment.

Type IV clinical trials, denoted by TCM₂₂, are typical TCM clinical trials adopting Chinese diagnostic and evaluating procedures pre- and posttreatment.

As can be seen from Table 1, for evaluation of a TCM under investigation, one may consider conducting a clinical trial that can be either type II (TCM₁₂) or type IV (TCM₂₂). In practice, however, WM type of clinical trials (type I and type III) and TCM type of clinical trials (type II and type IV) are very likely arriving at different conclusions on the test treatment under investigation due to some fundamental differences between WMs and TCMs. In the interest of testing for consistency between the Western way and the Chinese way for the evaluation of the TCM under investigation, the following study designs are useful:

Design A—Subjects will first be screened using the well-established Western study endpoints. Qualified subjects will then be randomly assigned to receive either a test treatment (T) or a control (C). In each treatment group, subjects will further be randomly split into two subgroups: one subgroup will be evaluated the Western way (WW) and the other subgroup will be evaluated the Chinese way (CW). Design A is illustrated in Fig. 1. Under this study design, not only the treatment effect can be evaluated by means of either the Western way or the Chinese way but also the consistency between WW and CW can be evaluated.

Design B—Subjects will first be screened by using the Chinese diagnostic procedure. Qualified subjects will then be randomly assigned to receive either a test treatment (T) or a control (C). In each treatment group, subjects will further be randomly split into

two subgroups: one subgroup will be evaluated the Western way (WW) and the other subgroup will be evaluated the Chinese way (CW). Design B is illustrated in Fig. 2. Under this study design, similarly, not only the treatment effect can be evaluated by means of either the Western way or the Chinese way, but also the consistency between WW and CW can be evaluated.

Design C—This design is a combination of Design A and Design B. Subjects will be first randomly split into two subgroups. Subjects in one subgroup will be screened using the well-established Western study endpoints, whereas subjects in the other subgroup will be screened by means of the Chinese diagnostic procedure. In each subgroup, qualified subjects will then be randomly assigned to receive either a test treatment (T) or a control (C). In each treatment group, subjects are further randomly split into two subgroups: one subgroup will be evaluated the Western way (WW) and the other subgroup will be evaluated the Chinese way (CW). Design C is illustrated in Fig. 3. Under this study design, the treatment effect in each subgroup can be evaluated by means of either the Western way or the Chinese way. In addition, the consistency between WW and CW across subgroups can be evaluated.

Alternative design—In practice, it may not be ethical if the disease under study is critical and/or life-threatening provided that a WM is available. Thus, alternatively, in 2009, Hsiao et al. proposed a randomized, placebo-control, crossover clinical trial or a parallel-group design consisting of three arms (i.e., the TCM under study, a WM as an active control, and a placebo).^[6] The three-arm, parallel-group design allows the establishment of non-inferiority/equivalence of the TCM compared to the active control (WM) and the demonstration of the superiority of the TCM with respect to the placebo. One of the advantages of a crossover clinical trial is that a comparison within each individual can be made, although it will take a longer time to complete the study. Although a crossover design requires a smaller sample size compared to a parallel-group design, there are some limitations for the use of crossover design. First, baselines

Fig. 1 Design for WM clinical trials comparing the Western way and the Chinese way

Fig. 2 Design for TCM clinical trials comparing the Western way and the Chinese way

Design C

Fig. 3 Design for combined WM and TCM clinical trials comparing the Western way and the Chinese way

prior to dosing may not be the same. Second, when a significant sequence effect is observed, we would not be able to isolate the effects of period effect, carry-over effect, and subject-by-treatment effect that are confounded to one another.

Preparation of Matching Placebo

In clinical development, double-blind, placebo-control, randomized clinical trials are often conducted for the evaluation of the safety and effectiveness of a test treatment under investigation. To maintain blindness, a matching placebo should be identical to the active drug in all aspects of size, color, coating, taste, texture, shape, and order except that it contains no active ingredient. In clinical trials, as an advanced technique available for formulation, a matching placebo is not difficult to make because most WMs contain a single active ingredient. Unlike WMs, TCMs usually consist of a number of components, which often have different tastes. In TCM clinical trials, the TCM under investigation is often encapsulated. However, the test treatment will be easily unblinded if either the patient or the Chinese doctor breaks the capsule. As a result, the preparation of a matching placebo in TCM clinical trials plays an important role for the success of the TCM clinical trials.

In 2011, Fai et al. pointed out that in many TCM clinical trials, it is very difficult to make a quality matching placebo to achieve the purpose of blinding.^[7] Ideally, the characteristics of the test drug and matching placebo should be identical in color, appearance, smell, and taste. The quality matching placebo should be identical to the test drug in physical form, sensory perception, packaging,

and labeling, and it should have no pharmaceutical activity. For this purpose, Fai et al. developed a placebo capsule to match an herbal medicine in terms of its physical form, chemical nature, appearance, packaging, and labeling. Based on the assessment results, the developed placebo capsule assessment results suggested that the placebo was found satisfactory in these aspects.^[7] Thus, Fai et al. concluded that a matching placebo could be created for a randomized controlled trial involving herbal medicine.^[7] In addition, Fai et al. also discussed the means to acquire patent for a developed matching placebo.^[7]

It should be noted that the preparation of matching placebo is extremely important to maintain the integrity of blinding to avoid any possible operational biases that may be introduced due to the knowledge of the treatment assignment. The oral dosage form of capsule is often considered for preparation of matching placebo for clinical trials involving Chinese herbal medicines as it may remove the strong smell and taste of the herbal medicines. However, one of the major challenges is that patients or clinicians will reveal the treatment assignments if they break the capsules. Thus, standard operating procedures (SOPs) for preventing patients and clinicians from breaking the capsules are necessarily developed.

Development of Clinical Endpoint

Unlike WMs, the primary study endpoints for the assessment of safety and effectiveness of a TCM are usually assessed subjectively by a quantitative instrument by experienced Chinese doctors. Although the quantitative instrument is developed by the community of Chinese

doctors and is considered a gold standard for the assessment of safety and effectiveness of the TCM under investigation, it may not be accepted by the Western clinicians due to fundamental differences in medical theory, perception, and practice. In practice, it is very difficult for a Western clinician to conceptually understand the clinical meaning of the difference detected by the subjective Chinese quantitative instrument. Consequently, whether the subjective quantitative instrument can accurately and reliably assess the safety and effectiveness of the TCM is always a concern to Western clinicians.

As an example, for the assessment of safety and efficacy of a drug product for the treatment of ischemic stroke, a commonly considered primary clinical endpoint is the functional status assessed by the so-called Barthel index. The Barthel index is an ordinal scale used to measure the performance of activities of daily living, which was introduced by Mahoney and Barthel.^[8] The Barthel index is a weighted functional assessment scoring technique composed of 10 items with a minimum total score of 0 (functional incompetence) and a maximum total score of 100 (functional competence). The Barthel index is a weighted scale measuring performance in self-care and mobility, which is widely accepted in ischemic stroke clinical trials. A patient may be considered a responder if his/her Barthel index is ≥ 60 . On the other hand, Chinese doctors usually consider a quantitative instrument developed by the Chinese medical community as the standard diagnostic procedure for assessment of ischemic stroke. The standard quantitative instrument is composed of six domains, which capture different information regarding patient's performance, functional activities, and signs and symptoms and status of the disease.

In practice, it is of interest to both Western clinicians and Chinese doctors how an observed clinically meaningful difference by the Chinese quantitative instrument can be translated to that of the primary study endpoint assessed by the Barthel index. To reduce the fundamental differences in medical theory/perception and practice, it is suggested that the subjective Chinese quantitative instrument be calibrated and validated with respect to that of the clinical endpoint assessed by the Barthel index before it can be used in TCM ischemic stroke clinical trials.

Validation of a Quality-of-Life-Like Instrument

In TCM medical practice, a Chinese doctor usually collects information from the patient with a certain disease through the four subjective diagnostic procedures as described earlier. The purpose of these subjective approaches is to collect information on various aspects of the disease under study such as signs, symptoms, patient's performance, and functional activities. In practice, a quality-of-life-like (QOL-like) instrument with a number of questions/items is often considered to quantitatively assess the treatment effect. These items are usually grouped to form subscales,

composite scores (domains), or an overall score for a simple and easy interpretation of the treatment effect. Since the items (subscales) in each subscale (composite score) are correlated, the structure of responses to a quantitative instrument is usually multidimensional, complex, and correlated.

In 1954, Guilford discussed several methods such as Cronbach's α for measuring the reliability of internal consistency of a quantitative instrument.^[9] In 1989, Guyatt et al. indicated that a quantitative instrument should be validated in terms of its validity, reproducibility, and responsiveness.^[10] In 1991, Hollenberg et al. discussed several methods for validation of a quantitative instrument, such as consensual validation, construct validation, and criterion-related validation.^[11] There is, however, no gold standard as to how a quantitative instrument should be validated. As indicated in the work of Chow and Liu^[3] in 2013, the validity of a quantitative instrument is the extent to which the instrument measures what is designed to measure. It is a measure of biasedness of the instrument.^[3] The biasedness of a quantitative instrument reflects the accuracy of the instrument. The reliability of a quantitative instrument measures the variability of the instrument, which directly relates to the precision of the instrument. On the other hand, the responsiveness of a quantitative instrument is usually referred to as the ability of the instrument to detect a difference of clinical significance within a treatment.

In 2009, Hsiao et al. considered a specific design for calibration/validation of the Chinese diagnostic procedure.^[6] In their proposed study design, qualified subjects are randomly assigned to receive either a TCM or a WM. Each patient will be evaluated by a Chinese doctor and a Western clinician independently, regardless of which treatment group he/she is in. As a result, there are four groups of data: (i) patients who receive TCM and are evaluated by a Chinese doctor, (ii) patients who receive TCM but are evaluated by a Western clinician, (iii) patients who receive WM but are evaluated by a Chinese doctor, and (iv) patients who receive WM and are evaluated by a Western clinician. Groups (iii) and (iv) are used to establish a standard curve for calibration between the TCM and the WM. Groups (i) and (ii) are then used to validate the Chinese diagnostic procedure based on the established standard curve.

Calibration of a Validated Instrument

Unlike WMs, the primary study endpoints for the assessment of safety and effectiveness of a TCM are usually assessed by a quantitative instrument or the four diagnostic procedures by experienced Chinese doctors. The assessment by a quantitative instrument has been criticized in many ways. First, it may not capture the true health status of the patients with diseases under study (e.g., by asking wrong questions). Second, it may not detect the effect of the test treatment under investigation. As an example,

consider a quantitative instrument with possible scores from 0 (perfect health) to 100 (worst possible disease status). Suppose the scores can be classified into the following categories of health status: *Health* (0–25), *Mild* (26–50), *Moderate* (51–75), and *Severe* (76–100). In this case, there is a significant difference between a patient with a score of 25 (*Health*) and a patient with a score of 26 (*Mild*) although they only differ by one point. On the other hand, a patient with a score of 26 and a patient with a score of 50 are both considered to have *Mild* disease status although they differ by 24 points. Thus, the assessment based on a quantitative instrument by experienced Chinese doctors is not only subjective but also lacks validity. Consequently, the reliability of the assessment is a concern, especially when there is evidence of large rater-to-rater variability.

Thus, although the quantitative instrument is developed by the community of Chinese doctors and is considered a gold standard for the assessment of safety and effectiveness of the TCM under investigation, it may not be accepted by the Western clinicians due to not only the lack of validity and reliability but also the interpretation of the assessment (or translation of assessment to well-established and widely accepted clinical endpoints). In practice, it is very difficult for a Western clinician to conceptually understand the clinical meaning of the difference detected by the subjective Chinese quantitative instrument due to fundamental differences in medical theory, perception, and practice.

Thus, for modernization or Westernization of TCMs, whether the subjective quantitative instrument can accurately and reliably assess the safety and effectiveness of the TCM is a concern for development of TCM. In practice, it is then suggested that a clinical trial be conducted to calibrate the subjective quantitative assessment against either life events or well-established clinical endpoints that are commonly used in the assessment of WMs. The clinical trials should consist of two arms: one arm will include subjects with diseases under study diagnosed by the subjective quantitative instrument and the other arm will include subjects diagnosed by Western diagnostic or testing procedures. Each subject posttreatment will be assessed by both Chinese doctors using the quantitative instrument and Western clinicians based on the well-established and widely accepted study endpoints.^[6]

Power Calculation for Sample Size Estimation

In clinical trials, sample size is usually selected to achieve a desired power for detecting a clinically meaningful difference in one of the primary study endpoints for the intended indication of the treatment under investigation.^[12] As a result, sample size calculation depends upon the primary study endpoint and the clinically meaningful difference that one would like to detect. Different primary study endpoints may result in very different sample sizes.

For illustration purposes, consider the example concerning a TCM for treatment of ischemic stroke, which

was developed with more than 30 years of clinical experience with humans. Suppose a sponsor would like to conduct a clinical trial to scientifically evaluate the safety and efficacy of the TCM the Western way compared to an active control (e.g., aspirin). Thus, the intended clinical trial is a double-blind, parallel-group, placebo-control, randomized trial. The primary clinical endpoint is the response rate (a patient is considered a responder if his/her Barthel index is ≥ 60) based on the functional status assessed by the Barthel index. Sample size calculation is performed based on the response rate after 4 weeks of treatment under the hypotheses of testing for superiority. As a result, a sample size of 150 patients per treatment group is required for achieving an 80% power for establishment of superiority of the TCM over the active control agent. Alternatively, we may consider the quantitative instrument developed by experienced Chinese doctors as the primary study endpoint for sample size calculation. Based on a pilot study, about 80% (79 out of 122) of ischemic stroke patients were diagnosed by one domain of the quantitative instrument. A patient is considered a responder if his/her domain score is ≥ 7 . Based on this primary study endpoint, a sample size of 90 per treatment group is required to achieve an 80% power for establishment of superiority.

The difference in sample size leads to the question of whether the use of the primary endpoint of response rate based on one domain of the Chinese quantitative instrument could provide substantial evidence of safety and effectiveness of the TCM under investigation.

PRACTICAL ISSUES

Before the test treatment under investigation can be used in humans, some practical issues regarding sufficient information of chemistry, manufacturing, and control (CMC); clinical pharmacology; and toxicology are necessarily considered.^[13] However, since most TCMs consist of multiple components with unknown pharmacological activities, information regarding CMC, clinical pharmacology, and toxicology is often difficult to obtain. In what follows, these difficulties are briefly described.

Test for Consistency

Unlike most WMs, TCMs usually consist of a number of components, which are extracted from herbal samples. The herbal samples are normally dried at 60°C to a constant weight, followed by grinding in a mortar and storing in a desiccator. For water-soluble substances, an appropriate amount of water is first added to the dried material and boiled for about 1 h. For alcohol-soluble substances, 60% ethanol is added and the mixture is extracted at 60°C for 1 h in an ultrasonic bath. After cooling to room temperature, the extract can be cleared by filtration through net or centrifugation at 12,000g for 10 min at 20°C, and the

supernatant is used for further applications. The pharmacological activities, interactions, and relative proportions of these components are usually unknown. In practice, TCM is usually prescribed subjectively by an experienced Chinese doctor. As a result, the actual dose received by each individual varies depending upon the signs and symptoms as perceived by the Chinese doctor. Although the purpose of this medical practice is to reduce the within-subject (or intra-subject) variability, it could also introduce nonnegligible variability such as variations from a component to a component and from a rater to a rater (a Chinese doctor to another). Consequently, reproducibility or consistency of clinical results is questionable. Thus, how to ensure the reproducibility or consistency of the observed clinical results has become a great concern to regulatory agencies in the review and approval process. It is also a great concern to the sponsor of the manufacturing process. To address the question of reproducibility or consistency, a valid statistical quality control process on the raw materials and final product is essential (see, e.g., the works of Tse^[14] and Lu et al.^[15]).

Stability Analysis

Most regulatory agencies require that the expiration dating period (or shelf life) of a drug product be indicated in the immediate container label before it can be released for use. To fulfill this requirement, stability studies are usually conducted in order to characterize the degradation of the drug product. For drug products with a single active ingredient, statistical methods for determination of drug shelf life are well established (see, e.g., the guidelines of FDA^[16] and ICH^[17]). However, for drug products with multiple components, regulatory requirements for estimation of drug shelf life are not available.

Following the concept of estimating the shelf life for drug products with a single active ingredient, two approaches are worth considering. First, we may (conservatively) consider the *minimum* of the shelf lives obtained from each component of the drug product. This approach is conservative, and yet may not be feasible due to the fact that (i) not all of the components of a TCM can be accurately and reliably quantitated, and (ii) the resultant shelf life may be too short to be useful. Alternatively, we may consider a two-stage approach for determination of drug shelf life. At the first stage, an attempt should be made to identify the most active component(s) whenever possible. A shelf life can then be obtained based on the method suggested in the FDA and ICH guidelines.^[16,17] At the second stage, the obtained shelf life is adjusted based on the relationship and/or interactions of the most active ingredient(s) and other components. As an alternative, Chow and Shao in 2007 proposed a statistical method for determining the shelf life of a TCM following a similar idea suggested by the FDA, assuming that the components are linear combinations of some factors.^[18]

Animal Studies

The purpose of animal studies is not only to study the possible toxicity in animals but also to suggest an appropriate dose for use in humans, assuming that the established animal model is predictive of the human model. For a newly developed drug product, animal studies are necessary. However, for some well-known TCMs, which have been used in humans for years and have a very mild toxicity profile, it is questionable whether animal studies are necessary. It is suggested that all components of TCMs as described in Chinese Pharmacopoeia (CP) be classified into several categories depending upon their potential toxicities and/or safety profiles as a basis for regulatory requirements for animal studies. In other words, for some well-known TCM components such as Ginseng, animal studies for testing toxicity may be waived depending upon the past experience of human use, although health risks or side effects following the proper administration of designated therapeutic dosages were not recorded in human use. Note that the German regulatory authority's herbal watchdog agency, commonly called Commission E, has conducted an intensive assessment of the peer-reviewed literature on some 300 common botanicals with respect to the quality of the clinical evidence and the uses for which the herb can be reasonably considered effective.^[19]

CONCLUDING REMARKS

Although TCM has a long history of being used in humans, little or no scientifically valid documentations are available for the demonstration of clinical safety and efficacy of the TCM. In the interest of modernization or Westernization of TCM development, as indicated by the FDA, substantial evidence regarding safety and effectiveness of the test treatment under investigation can only be obtained by conducting adequate and well-controlled clinical trials.^[5] In TCM clinical trials, however, it is a concern whether a TCM can be scientifically evaluated the Western way due to some fundamental differences between a WM and a TCM.

The purpose of this article is to provide some basic considerations for providing substantial evidence of clinical safety and efficacy of a TCM under investigation during the conduct of TCM clinical trials in the development of TCMs the Western way. These statistical considerations include selection of study design, preparation of matching placebo, development of study endpoint, validation of an instrument, calibration of a validated instrument, and power calculation for sample size estimation.

In addition, as discussed earlier, before a TCM under investigation can be used in humans, sufficient information regarding CMC, clinical pharmacology, and toxicology is necessarily provided. In practice, such information, which has the impact on the scientific validity for

the assessment of the TCM under investigation, is difficult, if not impossible, to obtain. Thus, it is suggested that some practical issues such as test for consistency, stability analysis for shelf-life estimation, and animal studies for toxicity be evaluated before the conduct of the intended TCM clinical trials.

Abstract

The purpose of this entry is not only to introduce Consortium for Globalization of Chinese medicine, but also to provide some basic considerations regarding practical issues that are commonly encountered when conducting a traditional Chinese medicine clinical trial the Western way.

Keywords: Calibration; Flexible dose; Global balance/harmony; Multiple components; Test for consistency; Validation.

INTRODUCTION

In recent years, as more and more innovator drug products are going off patent, the search for new medicines that treat critical and/or life-threatening diseases has become the center of attention of many pharmaceutical companies. This leads to the study of the potential use of promising traditional Chinese medicines (TCM), especially for those intended for treating critical and/or life-threatening diseases. A TCM is defined as a Chinese herbal medicine developed for treating patients with certain diseases as diagnosed by the four Chinese major techniques of inspection, auscultation and olfaction, interrogation, and pulse taking and palpation based on traditional Chinese medical theory of global dynamic balance among the functions/activities of all organs of the body. Unlike evidence-based clinical research and development of a Western medicine (WM), clinical research and development of a TCM is usually experience-based with anticipated variability due to subjective evaluation of the disease under study. The use of TCM in humans for treating various diseases has a history of more than five thousand years, although no scientific documentation is available regarding clinical evidence of safety and efficacy of these TCMs.

In the past several decades, regulatory agencies of both China and Taiwan have debated which direction the TCM should take—Westernization or modernization. The Westernization of TCM is referred to the adoption of the typical (Western) process of pharmaceutical research and development for scientific evaluation of the safety and effectiveness of the TCM products under investigation,

whereas the modernization of TCM is to evaluate the safety and effectiveness of TCM the Chinese way (i.e., different sets of regulatory requirements and evaluation criteria) scientifically. Although both China and Taiwan do attempt to build up an environment for the modernization of TCM, they seem to adopt the Westernization approach. In pursuit of advancing the TCM through the modernization way or the Westernization approach to benefit patients who suffer from critical and/or life-threatening diseases, a Consortium for Globalization of Chinese medicine (CGCM) was formed in 2003.

In practice, it is a concern whether a TCM can be scientifically evaluated the Western way due to some fundamental differences between a WM and a TCM. These include differences in formulation, medical practice, drug administration, diagnostic procedure and criteria for evaluation, and flexibility. Based on these differences, it is then of interest to researchers explore how to conduct a scientifically valid (i.e., an adequate and well-controlled) clinical trial for evaluation of the clinical safety and efficacy of the TCM under investigation. In addition, it is also of particular interest to the investigators how to translate an observed significant difference detected by the Chinese diagnostic procedure to a clinically meaningful difference based on some well-established clinical study endpoint. The purpose of this entry is not only to introduce CGCM, but also to provide some basic considerations regarding practical issues that are commonly encountered when conducting a TCM clinical trial the Western way.

The next section describes some fundamental differences between WM and TCM that have an impact on the Westernization of TCM. These fundamental differences

Table 1 Fundamental Differences between a WM and a TCM

Description	Western medicine (WM)	Traditional Chinese medicine (TCM)
Active ingredient	Single	Multiple
Dose	Fixed	Flexible
Diagnostic procedure	Objective; validated	Subjective; not validated
Therapeutic index	Well established	Not well established
Medical mechanism	Specific organs	Global dynamic balance/harmony among organs
Medical perception	Evidence-based	Experience-based
Statistics	Population	Individual

include the concept of global dynamic balance/harmony among organs of the body (TCM) versus local site action (WM); subjective diagnostic techniques of inspection, auscultation and olfaction, interrogation, pulse taking and palpation (TCM) versus objectively clinical evaluation (WM); and personalized flexible dose with multiple components (TCM) versus fixed dose of single active ingredient (WM). The section “Basic Considerations of TCM Clinical Trials” provides some basic considerations of TCM clinical trials. These basic considerations include study design, the validation of a quantitative instrument developed for the four major TCM diagnostic techniques, the use/preparation of matching placebo, and sample size calculation. Some practical issues commonly encountered when conducting a TCM clinical trial are discussed in the section “Other Issues in TCM Research and Development,” such as test for consistency in statistical quality control of raw material and/or final product, stability analysis, animal studies, regulatory requirements, and indication, label and packaging insert. The section “Consortium for Globalization of Chinese Medicine” introduces the organization of the Consortium for Globalization of Chinese Medicine and its recent development. Some concluding remarks, including future strategy and recommendations in TCM research and development, are given in the last section.

FUNDAMENTAL DIFFERENCES

As indicated earlier, the process for pharmaceutical research and development of Western medicines (WM) is well established, and yet it is a lengthy and costly process. This lengthy and costly process is necessary to ensure the efficacy, safety, quality, stability, and reproducibility of the drug product under investigation. For pharmaceutical research and development of a TCM, one may consider directly applying this well-established process to the TCM under investigation. However, this process may not be feasible due to some fundamental differences between a TCM and a WM, which are summarized in Table 1.

These fundamental differences are briefly described below.

Medical Theory/Mechanism and Practice

Medical Theory and Mechanism

TCM is a 3,000-year-old holistic medical system encircling the entire scope of human experience. It combines the use of Chinese herbal medicines, acupuncture, massage, and therapeutic exercise such as Qigong (the practice of internal *air*) and Taigie for both treatment and prevention of disease. With its unique theories of etiology, diagnostic systems, and abundant historical literature, TCM itself consists of Chinese culture and philosophy, clinical practice experience, and the use of many medical herbs.

Chinese doctors believe TCM functions in the body based on the eight principles (Table 2), five-element theory (Table 3), five *Zang* and six *Fu* (Table 4), and knowledge about channels and collaterals. The eight principles consist of *Yin* and *Yang* (i.e., negative and positive) (see also, Table 5), cold and hot, external and internal, and *Shi* and *Xu* (i.e., weak and strong). These eight principles help Chinese doctors to differentiate syndrome patterns. For instance, people with *Yin* will develop disease in a negative, passive, and cool way (e.g., diarrhea and back pain), whereas people with *Yang* will develop disease in an aggressive, active, progressive, and warm way (e.g., dry eyes, tinnitus, and night sweats). The five elements (earth, metal, water, wood, and fire) correspond to particular organs in the human body. Each element operates in

Table 2 Eight Principles

harmony with the others. Fig. 1 illustrates the operation relationships between the five elements.

The five Zang (or Yin organs) include heart (including the pericardium), lung, spleen, liver, and kidney, whereas the six Fu (or Yang organs) include gall bladder, stomach, large intestine, small intestine, urinary bladder, and three

cavities (i.e., chest, epigastrium, and hypogastrum). Zang organs can manufacture and store fundamental substances. These substances are then transformed and transported by Fu organs. TCM treatments involve a thorough understanding of the clinical manifestations of Zang-Fu organ imbalance as well as knowledge of appropriate acupuncture points and herbal therapy to rebalance or maintain the balance of the organs. The channels and collaterals are the representation of the organs of the body and are responsible for conducting the flow of energy and blood through the entire body.

The elements of TCM can also help to describe the etiology of disease including six exogenous factors (i.e., wind, cold, summer, dampness, dryness, and fire), seven emotional factors (i.e., anger, joy, worry, grief, anxiety, fear, and fright), and other pathogenic factors (Table 6). Once all of the information is collected and processed into a logical and workable diagnosis, the TCM doctor can determine the treatment approach.

Under the medical theory and mechanism described above, Chinese doctors believe that all of the organs within a healthy subject should reach the so-called *global dynamic balance or harmony* among organs. Once the global balance is broken at certain sites such as heart, liver, or kidney, some signs and symptoms then appear to reflect the imbalance at these sites. An experienced Chinese doctor usually assesses the causes of global imbalance before a TCM with flexible doses is prescribed to fix the problem. This approach is sometimes referred to as a personalized (or individualized) medicine approach.

Medical Practice

Different medical perceptions regarding signs and symptoms of certain diseases could lead to a different diagnosis

and treatment for the diseases under study. For example, the signs and symptoms of Type 2 diabetic subjects could be classified as the disease of *thirsty reduction* by Chinese doctors. The disease of Type 2 diabetes is not recognized by Chinese medical literature, although the disease has the same signs and symptoms as the well-known disease of thirsty reduction. This difference in medical perception and practice has an impact on the diagnosis and treatment of the disease.

In addition, we tend to see therapeutic effect of WM sooner than that of TCM. TCM is often considered for patients who have chronic diseases or non-life-threatening diseases. For critical and/or life-threatening diseases such as cancer or stroke, TCM is often used as the second-or third-line treatment with no other alternative treatments. In many cases such as patients with later phase of cancer, TCM is often used in conjunction with WM without the knowledge of the primary care physicians.

Techniques of Diagnosis

The Chinese diagnostic procedure for patients with certain diseases consists of four major techniques, namely, inspection, auscultation and olfaction, interrogation, and pulse taking and palpation (Table 7). All these diagnostic techniques aim mainly at providing an objective basis for differentiation of syndromes by collecting symptoms and signs from the patient. Inspection involves observing the patient's general appearance (strong or weak, fat or thin), mind, complexion (skin color), five sense organs (eye, ear, nose, lip, and tongue), secretions, and excretions.

Table 7 Four Major Techniques

English	Chinese
Four Major Techniques	四診
Inspection	望
Auscultation and olfaction	聞
Interrogation	問
Pulse taking and palpation	切

Auscultation involves listening to the voice, expression, respiration, vomit, and cough. Olfaction involves smelling the breath and body odor. Interrogation involves asking questions about specific symptoms and the general condition including history of the present disease, past history, personal life history, and family history. Pulse taking and palpation can help to judge the location and nature of a disease according to the changes of the pulse.

The Chinese diagnostic procedure of inspection, auscultation and olfaction, interrogation, and pulse taking and palpation is subjective, with large between rater variability (i.e., variability from one Chinese doctor to another). This subjectivity and variability will have an impact not only on the patient's evaluability but also the prescribability of TCM, which will be further discussed below.

Objective Versus Subjective Criteria for Evaluability

For evaluation of a WM, objective criteria based on some well-established clinical study endpoints are usually considered. For example, response rate (i.e., complete response plus

partial response based on tumor size) is considered a valid clinical endpoint for evaluating clinical efficacy of oncology drug products. Unlike WMs, Chinese diagnostic procedure for evaluation of a TCM is very subjective. The use of a subjective Chinese diagnostic procedure has raised the following issues. First, it is a concern whether the subjective Chinese diagnostic procedure can accurately and reliably evaluate clinical efficacy and safety of the TCM under investigation. Thus, it is suggested that the subjective Chinese diagnostic procedure should be validated in terms of its accuracy, precision, and ruggedness before it can be used in TCM clinical trials. A validated Chinese diagnostic procedure should be able to detect a clinically significant difference if the difference truly exists. On the other hand, it is not desirable to wrongly detect a difference when there is no difference.

In clinical trials, evaluation is usually based on some validated tools (instruments) such as laboratory tests. Test results are then evaluated against some normal ranges for abnormality. Thus, it is suggested that the Chinese diagnostic procedure must be validated in terms of validity and reliability, and its false positive and false negative rates, before it can be used for evaluation of clinical efficacy and safety of the TCM under investigation.

Treatment

TCM prescriptions typically consist of a combination of several components. The combination is usually determined based on the medical theory of global dynamic balance (or harmony) among organs, and the observations from the Chinese diagnostic procedure. The use of Chinese diagnostic procedure is to find out what caused the imbalance among these organs. The treatment is to re-install the balance among these organs. Thus, the dose and treatment duration are flexible in order to achieve the balance. This concept leads to the concept of so-called personalized (or individualized) medicine, which minimizes intra-subject variability.

Single Active Ingredient Versus Multiple Components

Most Western medicines (WMs) contain a single active ingredient. After drug discovery, an appropriate formulation (or dosage form) is necessarily developed so that the drug can be delivered to the site action in an efficient way. At the same time, an assay is necessarily developed to quantitate the potency of the drug. The drug is then tested on animals for toxicity, and humans (healthy volunteers) for pharmacological activities. Unlike WMs, TCMs usually consist of multiple components with certain relative proportions among the components. As a result, the typical approach for evaluation of single active ingredient for WMs is not applicable.

In practice, one may suggest evaluating the TCM component by component. However, this is not feasible due to the following difficulties. First, in practice, analytical

methods for quantitation of individual components are often not tractable. Thus, the pharmacological activities of these components are not known. It should be noted that the component that comprises the major proportion of the TCM may not be the most active component. On the other hand, the component that has the least proportion of the TCM may be the most active component of the TCM. In practice, it is not known which relative proportions among these components can lead to the optimal therapeutic effect of the TCM. In addition, the relative component-to-component and/or component by food interactions are usually unknown, which may have an impact on the evaluation of clinical efficacy and safety of the TCM.

Fixed Dose Versus Flexible Dose

Most WMs are usually administered in a fixed dose (say a 10mg tablets or capsule). On the other hand, because a TCM consists of multiple components with possible varied relative proportions among the components, a Chinese doctor usually prescribes the TCM with different relative proportions of the multiple components based on the signs and symptoms of the patient according to his or her best judgment following a subjective evaluation based on the Chinese diagnostic procedure. Thus, unlike a WM that is prescribed as a fixed dose, a TCM is often prescribed as an individualized flexible dose.

The approach of WM with a fixed dose is a population approach to minimize the between subject (or intersubject) variability, whereas the approach to TCM with an individualized flexible dose is to minimize the variability within each individual. In practice, it is a concern whether an individual flexible dose is compatible with a Western evaluation of the TCM. An individualized flexible dose depends heavily upon the Chinese doctor's subjective judgment, which may vary from one Chinese doctor to another. As a result, although an individualized flexible dose does minimize intra-subject variability, the variability from one Chinese doctor to another (i.e., the doctor-to-doctor or rater-to-rater variability) could be huge, and hence non-negligible.

Remarks

For the research and development of a TCM, before a TCM clinical trial is conducted, the following questions are necessarily asked.

- i. Will the TCM clinical trial be conducted by Chinese doctors alone, Western clinicians alone, Western clinicians who have some background of Chinese herbal medicine alone, or both Chinese doctors and Western clinicians?
- ii. Will traditional Chinese diagnostic and/or trial procedures be used throughout the TCM clinical trial?
- iii. Upon approval, is the TCM intended for use by Chinese doctors or Western clinicians?

With respect to the first two questions, if the TCM clinical trial is to be conducted by Chinese doctors alone, the following questions arise. First, should the Chinese diagnostic procedure be validated in order to provide an accurate and reliable assessment of the TCM? In addition, it is of interest to determine how an observed difference obtained from the Chinese diagnostic procedure can be translated to the clinical endpoint commonly used in similar WM clinical trials with the same indication. These two questions can be addressed statistically by the calibration and validation of the Chinese diagnostic procedure with respect to some well-established clinical endpoints for evaluation of Western medicines. If the TCM clinical trial is to be conducted by Western clinicians or Western clinicians who have some background of Chinese herbal medicine, the standards and consistency of clinical results as compared to those WM clinical trials are ensured. However, the good characteristics of TCM may be lost during the process of the conduct of the TCM clinical trials. On the other hand, if the TCM clinical trial is to be conducted by both Chinese doctors and Western clinicians, difference in medical practice and/or possible disagreement regarding the diagnosis, treatment, and evaluation are major concerns.

For the third question, if the TCM is intended for use of Chinese doctors but is conducted by Western clinicians, the difference in perception regarding how to prescribe the TCM is of great concern. The preparation of a package insert based on the clinical data could be a major issue, not only to the sponsor but also to regulatory authorities. Similar comments apply to the situation where the TCM is intended for use of Western clinicians but the trial is conducted by Chinese doctors.

As a result, it is suggested that the intention of use (i.e., labeling for the indication) be clearly evaluated when planning a TCM clinical trial. In other words, the sponsor needs to determine at the planning stage of a TCM clinical trial whether the TCM is intended for use of Western clinicians only, Chinese doctors only, or both Western clinicians and Chinese doctors in order to plan, for an adequate package insert of the target diseases under study.

BASIC CONSIDERATIONS OF TCM CLINICAL TRIALS

In this section, we describe some basic considerations that are necessary in order to ensure the success of a TCM clinical trial.

Study Design

To demonstrate clinical efficacy and safety of TCM under investigation, it is suggested that a randomized parallel-group, placebo-controlled clinical trial be conducted, as is done in WM. However, doing so may not be ethical if the disease under study is critical and/or life-threatening

provided that a WM is available. Alternatively, a randomized placebo-control crossover clinical trial or a parallel-group design consisting of three arms (i.e., the TCM under study, a WM as an active control, and a placebo) is recommended. The three-arm, parallel-group design allows the establishment of non-inferiority/equivalence of the TCM as compared to the active control (WM) and the demonstration of the superiority of the TCM with respect to the placebo. One of the advantages of a crossover clinical trial is that a comparison within each individual can be made, although it will take a longer time to complete the study. Although a crossover design requires a smaller sample size as compared to a parallel-group design, there are some limitations for the use of crossover design. First, baselines prior to dosing may not be the same. Second, when a significant sequence effect is observed, we would not be able to isolate the effects of period effect, carry over effects, and subject-by-treatment effect which are confounded to one another.

In many cases, factorial designs are used to evaluate the impact of specific components (with respect to the therapeutic effect) by fixing some of the components. For example, we may consider a parallel-group design comparing two treatment groups (one group is treated with the TCM with a specific component, and the other group is treated with the TCM without the specific component). Design of this kind may be useful to identify the most active component of the TCM with respect to the diseases under study. However, it does not address the possible drug-to-drug interactions among the components.

Validation of Quantitative Instrument

In TCM practice, a doctor usually collects information from the patient with a certain disease through the four subjective approaches described in the previous section. The purpose of these subjective approaches is to collect information on various aspects of the disease under study, such as signs, symptoms, patient's performance, and functional activities, so a quantitative instrument with a large number of questions/items is necessary and helpful. For simple analysis and easy interpretation, these questions are usually grouped to form subscales, composite scores (domains), or overall score. The items (or subscales) in each subscale (or composite score) are correlated. As a result, the structure of responses to a quantitative instrument is multidimensional, complex, and correlated. As mentioned above, a standardized quantitative tool (instrument) is necessary to reduce variability from one Chinese doctor to another (prior to the conduct of a clinical trial).

Guilford^[1] have discussed several methods such as Cronbach's α for measuring the reliability of internal consistency of a quantitative instrument. Guyatt et al.^[2] have indicated that a quantitative instrument should be validated in terms of its validity, reproducibility, and responsiveness. Hollenberg et al.^[3] have discussed several methods for

validation of a quantitative instrument, such as consensual validation, construct validation, and criterion-related validation. There is, however, no gold standard as to how a quantitative instrument should be validated. In this paper, we will focus on the validation of a quantitative instrument in terms of validity, reliability (or reproducibility) and responsiveness.^[4,5] As indicated in Chow and Shao,^[6] the validity of a quantitative instrument is the extent to which the instrument measures what is designed to measure. It is a measure of biasedness of the instrument. The biasedness of a quantitative instrument reflects the accuracy of the instrument. The reliability of a quantitative instrument measures the variability of the instrument, which directly relates to the precision of the instrument. On the other hand, the responsiveness of a quantitative instrument is usually referred to as the ability of the instrument to detect a difference of clinical significance within a treatment.

Hsiao et al.^[7] have considered a specific design for calibration/validation of the Chinese diagnostic procedure. In the proposed study design, qualified subjects are randomly assigned to receive either a TCM or a WM. Each patient is evaluated by a Chinese doctor and a Western clinician independently, regardless which treatment group he or she is in. As a result, there are four groups of data, namely (i) patients who receive TCM and evaluated by a Chinese doctor, (ii) patients who receive TCM but are evaluated by a Western clinician, (iii) patients who receive WM but are evaluated by a Chinese doctor, and (iv) patients who receive WM and are evaluated by a Western clinician. Groups (iii) and (iv) are used to establish a standard curve for calibration between the TCM and the WM. Groups (i) and (ii) are then used to validate the Chinese diagnostic procedure based on the established standard curve.

Clinical Endpoint

Unlike WMs, the primary study endpoints for assessment of safety and effectiveness of a TCM are usually assessed subjectively by a quantitative instrument by experienced Chinese doctors. Although the quantitative instrument is developed by the community of Chinese doctors and is considered a gold standard for assessment of safety and effectiveness of the TCM under investigation, it may not be accepted by the Western clinicians due to fundamental differences in medical theory, perception, and practice. In practice, it is very difficult for a Western clinician to conceptually understand the clinical meaning of the difference detected by the subjective Chinese quantitative instrument. Consequently, whether the subjective quantitative instrument can accurately and reliably assess the safety and effectiveness of the TCM is always a concern to Western clinicians.

Take for example the assessment of safety and efficacy of a drug product for treatment of ischemic stroke, a commonly considered primary clinical endpoint is the functional status assessed by the so-called Barthel index.

The Barthel index is a weighted functional assessment scoring technique composed of 10 items with a minimum score of 0 (functional incompetence) and a maximum score of 100 (functional competence). The Barthel index is a weighted scale measuring performance in self-care and mobility, which is widely accepted in ischemic stroke clinical trials. A patient may be considered a responder if his or her Barthel index is greater than or equal to 60. On the other hand, Chinese doctors usually consider a quantitative instrument developed by the Chinese medical community as the standard diagnostic procedure for assessment of ischemic stroke. The standard quantitative instrument is composed of six domains, which capture different information regarding patient's performance, functional activities, and signs and symptoms and status of the disease.

In practice, it is of interest to both Western clinicians and Chinese doctors how an observed clinically meaningful difference by the Chinese quantitative instrument can be translated to that of the primary study endpoint assessed by the Barthel index. To reduce the fundamental differences in medical theory/perception and practice, it is suggested that the subjective Chinese quantitative instrument be calibrated and validated with respect to that of the clinical endpoint assessed by the Barthel index before it can be used in TCM ischemic stroke clinical trials.

Matching Placebo

In clinical development, double-blind, placebo-control randomized clinical trials are often conducted for evaluation of the safety and effectiveness of a test treatment under investigation. To maintain blindness, a matching placebo should be identical to the active drug in all aspects of, size, color, coating, taste, texture, shape, and order except that it contains no active ingredient. In clinical trials, as advanced technique available for formulation, a matching placebo is not difficult to make because most WMs contain a single active ingredient. Unlike WMs, TCMs usually consist of a number of components, which often have different taste. In TCM clinical trials, the TCM under investigation is often encapsulated. However, the test treatment will be easily unblinded if either the patient or Chinese doctor breaks the capsule. As a result, the preparation of matching placebo in TCM clinical trials plays an important role for the success of the TCM clinical trials.

Sample Size Calculation

In clinical trials, sample size is usually selected to achieve a desired power for detecting a clinically meaningful difference in one of the primary study endpoints for the intended indication of the treatment under investigation.^[8] As a result, sample size calculation depends upon the primary study endpoint and the clinically meaningful difference that one would like to detect. Different primary study endpoints may result in very different sample sizes.

Consider the example concerning a TCM for treatment of ischemic stroke that was developed with more than 30 years clinical experience with humans. Suppose a sponsor would like to conduct a clinical trial to scientifically evaluate the safety and efficacy of the TCM the Western way as compared to an active control (e.g., aspirin). Thus, the intended clinical trial is a double-blind, parallel-group, placebo-control, randomized trial. The primary clinical endpoint is the response rate (a patient is considered a responder if his/her Barthel index is greater than or equal to 60) based on the functional status assessed by the Barthel index. Sample size calculation is performed based on the response rate after four weeks of treatment under the hypotheses of testing for superiority. As a result, a sample size of 150 patients per treatment group is required for achieving an 80% power for establishment of superiority of the TCM over the active control agent. Alternatively, we may consider the quantitative instrument developed by experienced Chinese doctors as the primary study endpoint for sample size calculation. Based on a pilot study, about 80% (79 out of 122) of ischemic stroke patients were diagnosed by one domain of the quantitative instrument. A patient is considered a responder if his or her domain score is greater than or equal to 7. Based on this primary study endpoint, a sample size of 90 per treatment group is required to achieve an 80% power for establishment of superiority.

The difference in sample size leads to the question of whether the use of the primary endpoint of response rate based on one domain of the Chinese quantitative instrument could provide substantial evidence of safety and effectiveness of the TCM under investigation.

OTHER ISSUES IN TCM RESEARCH AND DEVELOPMENT

Although TCM has a long history of use in humans, no scientifically valid documentations of its safety or effectiveness are available. As indicated by the U.S. Food and Drug Administration (FDA), substantial evidence regarding safety and effectiveness of the test treatment under investigation can only be obtained by conducting adequate and well-controlled clinical trials. However, before the test treatment under investigation can be used in human, sufficient information regarding chemistry, manufacturing, and control (CMC); clinical pharmacology; and toxicology must be provided.^[9] Because most TCMs consist of multiple components with unknown pharmacological activities, valid information regarding CMC, clinical pharmacology, and toxicology are difficult to obtain. In what follows, we briefly describe these difficulties.

Test for Consistency

As mentioned above, unlike most WMs, TCMs usually consist of a number of components that are extracted

from herbal samples. The herbal samples are normally dried at 60°C to a constant weight, followed by grinding in a mortar and storage in a desiccator. For water-soluble substances, an appropriate amount of water is first added to the dried material and boil for about one hour. For alcohol-soluble substances, 60% ethanol is added and the mixture is extracted at 60°C for one hour in an ultrasonic bath. After cooling to room temperature, the extract can be cleared by filtration through net or centrifugation at 12,000 g for 10 minutes at 20°C, and the supernatant is used for further applications. The pharmacological activities, interactions, and relative proportions of these components are usually unknown. In practice, TCM is usually prescribed subjectively by an experienced Chinese doctor. As a result, the actual dose received by each individual varies depending upon the signs and symptoms as perceived by the Chinese doctor. Although the purpose of this medical practice is to reduce the within-subject (or intra-subject) variability, it could also introduce non-negligible variability such as variations from component-to-component and from rater-to-rater (a Chinese doctor to another). Consequently, reproducibility or consistency of clinical results is questionable. Thus, ensuring the reproducibility or consistency of the observed clinical results has become a great concern to regulatory agencies in the review and approval process. It is also a great concern to the sponsor of the manufacturing process. To address the question of reproducibility or consistency, a valid statistical quality control process on the raw materials and final product is suggested.

Chow et al.^[10] and Tse et al.^[13] have proposed a statistical quality control (QC) method to assess a proposed consistency index of raw materials, which are from different resources and/or final product, which may be manufactured at different sites. The consistency index is defined as the probability that the ratio of the characteristics (e.g., extract) of the most active component among the multiple components of a TCM from two different sites (locations) is within a limit of consistency. The consistency index closest to 1 indicates that the components from the two sites or locations are almost identical. The idea for testing consistency is to construct a 95% confidence interval for the proposed consistency index under a sampling plan. If the constructed 95% confidence lower limit is greater than a pre-specified QC lower limit, then we claim that the raw materials or final product has passed the QC and hence can be released for further process or use. Otherwise, the raw materials and/or final product should be rejected.

Let U and W be the characteristics of the most active component among the multiple components of a TCM from two different sites, where $X = \log U$ and $Y = \log W$ follows normal distributions with means μ_X , μ_Y and variances V_X , V_Y , respectively. Similar to the idea of using $P(X < Y)$ to assess reliability in statistical quality control,^[11,12] Tse et al.^[10] have proposed the following probability as an

index to assess the consistency of raw materials and/or final product from two different sites

$$p = P\left(1 - \delta < \frac{U}{W} < \frac{1}{1 - \delta}\right), \quad (1)$$

where $0 < \delta < 1$ and is defined as a limit that allows for consistency. Tse et al.^[10] refer p as the consistency index. Thus p tends to 1 as δ tends to 1. For a given δ , if p is close to 1, materials U and W are considered to be identical. It should be noted that a small δ implies the requirement of high degree of consistency between material U and materials W . In practice, it may be difficult to meet this narrow specification for consistency. Under the normality assumption of $X = \log U$ and $Y = \log W$, p is given by

$$p = \Phi\left(\frac{-\log(1 - \delta) - (\mu_X - \mu_Y)}{\sqrt{V_X + V_Y}}\right) - \Phi\left(\frac{\log(1 - \delta) - (\mu_X - \mu_Y)}{\sqrt{V_X + V_Y}}\right),$$

where $\Phi(z_0) = P(Z < z_0)$ with Z being a standard normal random variable. Therefore, the consistency index p is a function of the parameters

$$\theta = (\mu_X, \mu_Y, V_X, V_Y),$$

Suppose that observations $X_i = \log U_i, i = 1, \dots, n_X$, $Y_i = \log W_i, i = 1, \dots, n_Y$ are collected in an assay study. Then, using the invariance principle, the maximum likelihood estimator (MLE) of p can be obtained as

$$\hat{p} = \Phi\left(\frac{-\log(1 - \delta) - (\bar{X} - \bar{Y})}{\sqrt{\hat{V}_X + \hat{V}_Y}}\right) - \Phi\left(\frac{\log(1 - \delta) - (\bar{X} - \bar{Y})}{\sqrt{\hat{V}_X + \hat{V}_Y}}\right), \quad (2)$$

where

$$\bar{X} = \frac{1}{n_X} \sum_{i=1}^{n_X} X_i, \bar{Y} = \frac{1}{n_Y} \sum_{i=1}^{n_Y} Y_i, \hat{V}_X = \frac{1}{n_X} \sum_{i=1}^{n_X} (X_i - \bar{X})^2,$$

$$\text{and } \hat{V}_Y = \frac{1}{n_Y} \sum_{i=1}^{n_Y} (Y_i - \bar{Y})^2.$$

In other words, $\hat{p} = h(\theta) = h(\bar{X}, \bar{Y}, \hat{V}_X, \hat{V}_Y)$. Furthermore, it can be easily verified that the following asymptotic result holds. It can be verified that $\hat{p}$ is asymptotically normal with mean $E(\hat{p})$ and variance $Var(\hat{p})$. That is,

$$\frac{\hat{p} - E(\hat{p})}{\sqrt{Var(\hat{p})}} \rightarrow N(0, 1), \quad (3)$$

where $E(\hat{p}) = p + B(p) + o(\frac{1}{n})$ and $Var(\hat{p}) = C(p) + o(\frac{1}{n})$, where $B(p)$ and $C(p)$ are some functions of p .^[13] As a result, an approximate $(1 - \alpha) \times 100\%$ confidence interval for p , i.e., $(LL(\hat{p}), UL(\hat{p}))$, can be obtained as follows

$$LL(\hat{p}) = \hat{p} - B(\hat{p}) - z_{\alpha/2} \sqrt{C(\hat{p})}, \text{ and} \quad (4)$$

$$UL(\hat{p}) = \hat{p} - B(\hat{p}) + z_{\alpha/2} \sqrt{C(\hat{p})}.$$

where $z\alpha$ is the upper α -percentile of a standard normal distribution. In terms of consistency, Tse et al.^[10] proposed the following quality control (QC) criterion. If the probability that the lower limit $LL(\hat{p})$ of the constructed $(1 - \alpha) \times 100\%$ confidence interval of p is greater than or equal to a pre-specified quality control lower limit, say, QC_L , exceeds a pre-specified number β (say $\beta = 80\%$), then we claim that U and W are consistent or similar. In other words, U and W are consistent or similar if $P(QC_L \leq LL(\hat{p})) \geq \beta$, where β is a pre-specified constant. In practice, it is necessary to select a sample size to ensure that there is a high probability, say β , of consistency between U and W when in fact U and W are consistent. It is suggested that the sample size is chosen such that there is more than 80% chance that the lower confidence limit of p is greater than or equal to the QC lower limit, i.e. $\beta = 0.8$. In other words, the sample size is determined such that

$$P\{QC_L \leq LL(\hat{p})\} \geq \beta. \quad (5)$$

Using Eq. (5), this leads to

$$P\{QC_L \leq \hat{p} - B(\hat{p}) - z_{\alpha/2} \sqrt{Var(\hat{p})}\} \geq \beta.$$

Thus,

$$P\{QC_L + z_{\alpha/2} \sqrt{Var(\hat{p})} - p \leq \hat{p} - p - B(p)\} \geq \beta.$$

This gives

$$P\left\{\frac{QC_L - p}{\sqrt{Var(\hat{p})}} + z_{\alpha/2} \leq \frac{\hat{p} - p - B(p)}{\sqrt{Var(\hat{p})}}\right\} \geq \beta.$$

Therefore, the sample size required for achieving a probability higher than β can be obtained by solving the following equation:

$$\frac{QC_L - p}{\sqrt{Var(\hat{p})}} + z_{\alpha/2} \leq -z_{1-\beta}. \quad (6)$$

Assuming that $n_X = n_Y = n$, then the common sample size is given by

$$n \geq \frac{(z_{1-\beta} + z_{\alpha/2})^2}{(p - QC_L)^2} \left\{ \left(\frac{\partial \hat{p}}{\partial \mu_X} \right)^2 V_X + \left(\frac{\partial \hat{p}}{\partial \mu_Y} \right)^2 V_Y + \left(\frac{\partial \hat{p}}{\partial V_X} \right)^2 (2V_X^2) + \left(\frac{\partial \hat{p}}{\partial V_Y} \right)^2 (2V_Y^2) \right\}.$$

The above result suggests that the required sample size will depend on the choices of α , β , V_x , V_y , $\mu_x - \mu_y$ and $p - QC_L$.

It should be noted that Tse et al.^[10] only focus on single (i.e., the most active) component assuming that the most active component can be quantitatively identified among the multiple active components. Lu, Chow, and Tse^[14] extend the results to the case of two correlative components following similar idea. Various sampling plans are obtained for various combinations of study parameters to reflect real practice in quality control of traditional Chinese medicine.

Stability Analysis

Most regulatory agencies require that the expiration dating period (or shelf life) of a drug product must be indicated in the immediate container label before it can be released for use. To fulfill this requirement, stability studies are usually conducted in order to characterize the degradation of the drug product. For drug products with a single active ingredient, statistical methods for determination of drug shelf life are well established.^[15,16] However, regulatory requirements for estimation of drug shelf life for drug products with multiple components are not available.

Following the concept of estimating shelf life for drug products with single active ingredient, two approaches are worthy considering. First, we may (conservatively) consider the minimum of the shelf-lives obtained from each component of the drug product. This approach is conservative, and yet may not be feasible due to the fact that (i) not all of the components of a TCM can be accurately and reliably quantitated, and (ii) the resultant shelf life may be too short to be useful.^[17] Alternatively, we may consider a two-stage approach for determination of drug shelf life. At the first stage, an attempt should be made to identify the most active component(s) whenever possible. A shelf life can then be obtained based on the method suggested in the FDA and ICH guidelines. At the second stage, the obtained shelf life is adjusted based on the relationship and/or interactions of the most active ingredient(s) and other components.

Alternatively, Chow and Shao^[18] have proposed a statistical method for determining the shelf life of a TCM following a similar idea suggested by the FDA, assuming that the components are linear combinations of some factors. Let $y(t)$ denote the p dimensional vector whose k th component is the potency of the k th ingredient at time t after the manufacture of a given TCM, $k = 1, \dots, p$. Assume that, for any t ,

$$y(t) - E[y(t)] = LF_t + \varepsilon_t, \quad (7)$$

where L is a $p \times q$ nonrandom unknown matrix of full rank, F_t and ε_t are unobserved independent random vectors of dimensions q and p , respectively, $E(F_t) = 0$, $Var(F_t) = I_q$ (the identity matrix of order q), $E(\varepsilon_t) = 0$, $Var(\varepsilon_t) = \Psi$, and Ψ

is an unknown diagonal matrix of order p . Let $z(t) = (L'L)^{-1}L'y(t)$. It follows from Eq. (7) that

$$z(t) - E[z(t)] = F_t + (L'L)^{-1}L'\varepsilon_t. \quad (8)$$

Now, let $x(t)$ be an s dimensional covariate vector associated with $y(t)$ at time t . Chow and Shao^[18,19] assume the following model at any time t :

$$E[y(t)] = Bx(t), Var[y(t)] = \Sigma, \quad i = 1, \dots, m, j = 1, \dots, n, \quad (9)$$

where B is a $p \times s$ matrix of unknown parameters and $\Sigma > 0$ is an unknown $p \times p$ positive definite covariate matrix. Since $z(t) = (L'L)^{-1}L'y(t)$, it follows from Eq. (9) that

$$E[z(t)] = \gamma'x(t) = (L'L)^{-1}L'Bx(t), \quad i = 1, \dots, m, j = 1, \dots, n, \quad (10)$$

where $\gamma = B'L(L'L)^{-1}$. Suppose that we independently observe data y_{ij} , $i = 1, \dots, m, j = 1, \dots, n$, where y_{ij} is the j th replicate of $y(t_i)$ and $t_1, \dots, t_m$ are designed time points for the stability analysis. Define

$$x_i = x(t_i), z_{ij} = (L'L)^{-1}L'y_{ij}, \quad i = 1, \dots, m, j = 1, \dots, n \quad (11)$$

Consider the case where $q = 1$. If z_{ij} 's are observed, according to FDA,^[15] the expiration dating period (or shelf life) is given by

$$\tau = \inf\{t : l(t) \leq \eta\}, \quad (12)$$

where η is the lower product specification limit as specified in the USP/NF. However, z_{ij} 's are not observed but y_{ij} 's. Thus, the lower confidence bound $l(t)$ in (12) needs to be modified as follows

$$l(t) = \hat{\gamma}'x(t) - t_{0.95, mn-s} \sqrt{x(t)'Vx(t)}, \quad (13)$$

where

$$V = \frac{mn-1}{mn} \sum_{i=1}^m \sum_{j=1}^n (\hat{\gamma}_{i,j} - \hat{\gamma})(\hat{\gamma}_{i,j} - \hat{\gamma})',$$

in which $\hat{\gamma}_{i,j}$ is the estimator of γ with the (i,j) th data point deleted. For the case where $1 < q \leq p$, let $\hat{B}$ be least squares estimator of B , λ_k be the k th largest eigenvalue of the sample covariance matrix based on $y_{ij} - \hat{B}x_i$, $i = 1, \dots, m, j = 1, \dots, n$, and e_k be the normalized eigenvector corresponding to λ_k . Then, estimator $\hat{L}$ of L is the $p \times q$ matrix whose k th column is $\lambda_k e_k$, $k = 1, \dots, q$. Let $\hat{\gamma}_k$ be the k th column of $\hat{\gamma} = \hat{B}'\hat{L}(\hat{L}'\hat{L})^{-1}$, which is an $s \times q$ matrix. Thus we have

$$l_k(t) = \hat{\gamma}_k'x(t) - t_{0.95/q, mn-s} \sqrt{x(t)'V_kx(t)}, \quad (14)$$

where

$$V_k = \frac{mn-1}{mn} \sum_{i=1}^m \sum_{j=1}^n (\hat{\gamma}_{k,i,j} - \hat{\gamma}_k)(\hat{\gamma}_{k,i,j} - \hat{\gamma}_k)',$$

in which $\hat{\gamma}_{k,i,j}$ is the same as $\hat{\gamma}_k$ but calculated with the (i,j) th data point deleted. Then, $l_k(t)$, $k = 1, \dots, q$ are approximate 95% simultaneous lower confidence bounds for $\zeta(t)$, $k = 1, \dots, q$, where $\zeta_k(t)$ is the k th component of $E[z(t)] = \gamma'x(t)$. An estimated shelf life is then given by

$$\tau = \min_{k=1, \dots, q} \tau_k,$$

where τ_k is defined by the right-hand side of Eq. (12) with $l(t)$ replaced by $l_k(t)$ and is in fact an estimated shelf life for the k th component of z with confidence level $(1 - 0.05/q)\%$.

Animal Studies

The purpose of animal studies is not only to study possible toxicity in animals, but also to suggest an appropriate dose for use in humans, assuming that the established animal model is predictive of the human model. For a newly developed drug product, animal studies are necessary. However, for some well-known TCMs, which have been used in humans for years and have a very mild toxicity profile, it is questionable whether animal studies are necessary. It is suggested that all components of TCMs as described in Chinese Pharmacopoeia (CP) be classified into several categories depending upon their potential toxicities and/or safety profiles as a basis for regulatory requirements for animal studies. In other words, for some well-known TCM components such as Ginseng, animal studies for testing toxicity may be waived depending upon past experience of human use, although health risks or side effects following the proper administration of designated therapeutic dosages were not recorded in human use. Note that the German regulatory authority's herbal watchdog agency, commonly called Commission E, has conducted an intensive assessment of the peer-reviewed literature on some three hundred common botanicals with respect to the quality of the clinical evidence and the uses for which the herb can be reasonably considered effective.^[20]

Regulatory Requirements

Although the use of TCMs in humans has a long history, there have been no regulatory requirements regarding the assessment of safety and effectiveness of the TCMs until recently. For example, the regulatory authorities of both China and Taiwan have published guidelines/guidances for clinical development of TCMs.^[21–23] In addition, the U.S. FDA has also published a guidance for botanical drug products.^[24] These regulatory requirements for TCM research and development, especially for clinical development, are very similar to well-established guidelines/guidances for pharmaceutical research and development for WMs. It is a concern whether these regulatory requirements and the corresponding statistical methods are feasible for research and development of TCM, based on the fact that there are

so many fundamental differences in medical practice, drug administration, and diagnostic procedure. As a result, it is suggested that current regulatory requirements and the corresponding statistical methods should be modified in order to reflect these fundamental differences.

It is strongly recommended that regulatory requirements for development, review and approval process for Premarin (conjugated estrogens tablets, USP) be consulted because Premarin is a WM consisting of multiple components and is thus similar to a TCM.^[25–30] Premarin, which contains multiple components of estrone, equilin, 17α -dihydroequilin, 17α -estradiol, and 17β -dihydroequilin, is intended for treatment of moderate to severe vasomotor symptoms associated with the menopause. The experience with Premarin is helpful in developing appropriate guidelines/guidances for TCM drug products with multiple components.

Indication/Label

As indicated earlier, it is very important to clarify the intention for the use of a TCM (by Chinese doctors alone, Western clinicians alone, or both Chinese doctors and Western clinicians) once it is approved by the regulatory agencies. If a TCM is intended for use by Chinese doctors alone, the clinical trials conducted for obtaining substantial evidence should reflect medical theory of TCM and medical practice of Chinese doctors. The label should provide sufficient information as to how to prescribe the TCM the Chinese way. On the other hand, if the TCM under investigation is intended for use by Western clinicians alone, patients under study should be evaluated based on clinical study endpoints for safety and efficacy the Western way. Consequently, the label should provide sufficient information for prescribing the TCM the Western way. If the TCM is intended for both Western clinicians and Chinese doctors, patients are necessarily evaluated by both Western clinical study endpoints and Chinese diagnostic procedures (e.g., some standardized quantitative instrument) provided that the Chinese diagnostic procedure has been calibrated and validated against the well-established Western clinical endpoint. In this case, there is a clear understanding how an observed difference by Chinese diagnostic procedure can be translated to a clinical effect which is familiar to Western clinicians, and vice versa.

CONSORTIUM FOR GLOBALIZATION OF CHINESE MEDICINE

As indicated earlier, in pursuit of advancing the TCM to benefit patients who suffer from critical and/or life-threatening diseases, a Consortium for Globalization of Chinese Medicine (CGCM) was formed at the University of Hong Kong in 2003. The goals of the consortium are multifold. First, the CGCM is to provide an environment for development of platform technologies required

for advancing Chinese herbal medicine by joint efforts. Second, it is to facilitate the interaction and collaboration among different institutes in advancing Chinese herbal medicine by information sharing. Third, it is to promote high-quality research and development of Chinese medicine internationally. In addition, it is to assist industry and regulatory agencies worldwide in (i) methodology development in TCM research and development and (ii) guidances/guidelines development for evaluation and approval of TCM regulatory submissions. More details can be found at <http://www.tcmmedicine.org>.

The CGCM aims at to establish a network among researchers from academia, industry, and regulatory agencies under an academic collaboration arrangement focusing on two main areas. The first area is for the development of a centralized database of Chinese medicine that is completed with formulations, botanical ingredients, and phytochemical substances along with associated biological information on traditional and modern therapeutic indication, clinical information, animal pharmacology, biochemical activities, toxicities, and manufacturing information. The other area of focus is for the standardization and adoption of a modern quality-control platform for chemical and biological fingerprinting of botanical drugs for scientific and regulatory purpose. The Consortium had 13 institutional members when it was founded in 2003. As of August 2005, it has grown to 32 institutional members worldwide, including Columbia University and Yale University in the United States.

To achieve the goal of globalization of Chinese medicine, the CGCM has established six working groups including (i) quality control, (ii) informatics, (iii) herbal resources, (iv) clinical, (v) external affairs and industrial liaison, and (vi) intellectual property. The Quality Control Working Group develops strategy and appropriate methodology including acceptance criteria, sampling plan, and testing procedure for assuring consistency of raw materials, in-process materials, and final products in post-approval manufacturing process. The Informatics Working Group investigates possible biomarkers such as PK/PD markers or genomic markers for efficacy and safety in traditional Chinese medicine clinical trials. The Working Group for Herbal Resources not only identifies resources of Chinese herbs worldwide, but also determines potential differences in the same species of herbs. The External Affairs and Industrial Liaison Working Group seeks collaboration in TCM research development with the pharmaceutical industry and/or research organizations such as the National Institutes of Health (NIH) of the United States of America. The Working Group for Intellectual Property is developing strategies for patent protection. The efforts of the six working groups will lead advance in TCM research and development in the next century. However, it is also strongly suggested that a working group regarding regulatory requirements for review and approval of TCM be established to assist the sponsors to bring their

promising (efficacious and safe) TCM products to the marketplace. The Working Group for Regulatory Affairs should be a collaborative team that includes regulatory agencies from Taiwan, China, the United States, Europe (such as Germany), and Japan for a harmonized regulatory requirements.

CONCLUDING REMARKS

As indicated earlier, a TCM is defined as a Chinese herbal medicine developed for treating patients with certain diseases as diagnosed by the four major techniques of inspection, auscultation and olfaction, interrogation, and pulse taking and palpation based on traditional Chinese medical theory of global balance among the functions/activities of all organs of the body. When conducting a TCM clinical trial, it is suggested that the fundamental differences between a WM and a TCM, as described in the section "Fundamental Differences," should be evaluated carefully for a valid and unbiased assessment of the safety and effectiveness of the TCM under investigation.

One of the key issues in TCM research and development is the clarification of differences between Westernization of TCM and modernization of TCM. For Westernization of TCM, we follow regulatory requirements at critical stages of the process for pharmaceutical development including drug discovery, formulation, laboratory development, animal studies, clinical development, manufacturing process validation and quality control, regulatory submission, review, and process, despite the fundamental differences between WM and TCM. For modernization of TCM, it is suggested that regulatory requirements should be modified in order to account for the fundamental differences between WM and TCM. In other words, we still ought to be able to see if TCM is really working with modified regulatory requirements using Western clinical trials as a standard for comparison.

In practice, it is recognized that WMs tend to achieve the therapeutic effect sooner than that of TCMs for critical and/or life-threatening diseases. TCMs are found to be useful for patients with chronic diseases or non-life-threatening diseases. In many cases, TCMs have shown to be effective in reducing toxicities or improving safety profile for patients with critical and/or life-threatening diseases. As a strategy for TCM research and development, it is suggested that (i) TCM be used in conjunction with a well-established WM as a supplement to improve its safety profile and/or enhance therapeutic effect whenever possible, and that (ii) TCM should be considered as the second- or third-line treatment for patients who fail to respond to the available treatments. However, some sponsors are interested in focusing on the development of TCM as a dietary supplement due to (i) the lack or ambiguity of regulatory requirements, (ii) the lack of understanding of the medical theory/mechanism of TCM, (iii) the confidentiality

of non-disclosure of the multiple components, and (iv) the lack of understanding of pharmacological activities of the multiple components of TCM.

Because TCM consists of multiple components that may be manufactured from different sites or locations, the post-approval consistency in quality of the final product is both a challenge to the sponsor and a concern to the regulatory authority. As a result, some post-approval tests, such as tests for content uniformity, weight variation, and/or dissolution and (manufacturing) process validation, must be performed for quality assurance before the approved TCM can be released for use.

Traditional Chinese Medicine (TCM): Unified Approach for Evaluation

Bin Cheng

Department of Biostatistics, Columbia University, New York, New York, U.S.A.

Shein-Chung Chow

Department of Biostatistics and Bioinformatics, Duke University School of Medicine, Durham, North Carolina, U.S.A.

INTRODUCTION

In recent years, as more and more innovative drug products are going off patent protection, the search for new medicines that treat critical and/or life-threatening diseases such as cardiovascular diseases and cancer has become the center of attention of many pharmaceutical companies and research organizations such as the National Institutes of Health (NIH). This leads to the study of the potential use of promising traditional Chinese medicines (TCMs), especially for critical and/or life-threatening diseases. Randomized clinical trial (RCT) was used to assess the effect of Chinese herb medicine in treating the irritable bowel syndrome.^[1] However, RCT is not in common use when studying TCM. There are fundamental differences between Western medicines and TCMs in terms of diagnostic procedures, therapeutic indices, medical mechanism, medical theory, and method practice.^[2–4] Besides, TCM often consists of multiple components with flexible dose.

Chinese doctors believe that all of the organs within a healthy subject should reach the so-called *global dynamic balance and harmony* among organs. Once the global balance is broken at certain sites such as the heart, liver, or kidney, some signs and symptoms will appear to reflect the imbalance at these sites. The collective signs and symptoms are then used to determine what disease the individual has contracted. An experienced Chinese doctor usually assesses the causes of global imbalance before a TCM with flexible doses is prescribed to fix the problem. This approach is sometimes referred to as a personalized (or individualized) medicine approach. In practice, TCMs consider inspection, auscultation and olfaction, interrogation, and pulse taking and palpation as the primary diagnostic procedures. The scientific validity of these subjective and experience-based diagnostic procedures has been criticized due to lack of reference standards and anticipated large evaluator-to-evaluator (i.e., Chinese doctor-to-Chinese doctor) variability. For a systematic discussion of the statistical issues of TCM, see the work of Chow.^[4]

In this article, we attempt to propose a unified approach to developing a composite dissimilarity index based on a

number of indices collected from a treated subject and a healthy control, respectively, under the concept of global dynamic balance among organs. Dynamic balance among organs can be defined as follows: Following the concept of testing bioequivalence or biosimilarity, if the 95% confidence upper bound is less than some health limit, then the conclusion is that the treatment achieves dynamic balance among the organs of the subject; hence, it is considered as efficacious. If we fail to reject the null hypothesis, then the conclusion is that the treatment is not efficacious since there is still a signal of illness, i.e., some of signs and symptoms are still out of the health limit.

METHOD

Dissimilarity Index as an Efficacy Measure

Let $X_T = (X_{T1}, \dots, X_{Tk})$ and $X_H = (X_{H1}, \dots, X_{Hk})$ be the k -dimensional health profiles of a subject who is under treatment of TCM and a subject who is a healthy control, respectively. The components X_{Ti} of a health profile could be either continuous or ordinal, and even if it is continuous, its distribution may not be normal. The dimension of the health profile k is potentially high. Under this formulation, a TCM treatment is considered as efficacious if the health profile of subjects who receive treatment is not significantly different from the one of a healthy subject, possibly age and gender matched if needed. To this end, we define a dissimilarity index θ as a kind of pseudo distance between the profile of a treated subject and the profile of a healthy subject. Specifically, let μ_T and μ_H be the mean health profiles of a treated subject and a healthy subject, respectively, and let Σ_T and Σ_H be the covariance matrices of a treated subject and a healthy subject, respectively. Let $\lambda_1(\Sigma)$ be the largest eigenvalue of a symmetric matrix Σ . Define the dissimilarity index as

$$\theta = \frac{(\mu_T - \mu_H)^T (\mu_T - \mu_H) + \lambda_1(\Sigma_T) - \lambda_1(\Sigma_H)}{\max\{\sigma_0^2, \lambda_1(\Sigma_H)\}}, \quad (1)$$

where σ_0^2 is a known constant.

The above definition of dissimilarity index has an interesting connection with principal component analysis. To see this, imagine that X_T and X_H are multivariate normal. Then, $(\mu_T - \mu_H)^T (\mu_T - \mu_H)$ is the squared mean of the first principal component of $X_T - X_H$, $\lambda_1(\Sigma_T)$ is the variance of the first principal component of X_T , and $\lambda_1(\Sigma_H)$ is the variance of the first principal component of X_H . A small θ implies two things. First, it implies a small difference between the mean health profiles μ_T and μ_H , relative to the maximal variance of a healthy profile X_H . Second, it implies that the maximal variance of the diseased profile X_T is at least not much greater than the maximal variance of the healthy profile X_H . Therefore, a small dissimilarity index can be viewed as evidence for efficacy of a treatment.

The efficacy of a treatment could be formulated as a test for equivalence with the health profile of a healthy control. Let X_T denote the health profile of a diseased subject at the completion of the treatment in Eq. 1. The efficacy is claimed if a test rejects the following H_0 :

$$H_0: \theta \geq \varepsilon \text{ versus } H_1: \theta < \varepsilon, \quad (2)$$

where ε is a known positive threshold.

Assessing Treatment Effect of TCM through Dissimilarity Index

Let

$$\gamma = (\mu_T - \mu_H)^T (\mu_T - \mu_H) + \lambda_1(\Sigma_T) - \lambda_1(\Sigma_H) - \in \max\{\sigma_0^2, \lambda_1(\Sigma_H)\}. \quad (3)$$

Then, testing Eq. 2 is equivalent to testing

$$H_0: \gamma \leq 0 \text{ versus } H_1: \gamma < 0. \quad (4)$$

We construct an asymptotic test via the duality between hypothesis test and confidence interval. Specifically, we construct a 95% approximate confidence upper bound for γ based on two independent random samples $X_{Ti} = (X_{Ti1}, \dots, X_{Tki})^T$, $i = 1, \dots, n_T$, $X_{Hj} = (X_{Hj1}, \dots, X_{Hkj})^T$, $j = 1, \dots, n_H$, and reject the H_0 if this 95% confidence upper bound is smaller than 0.

Let B be a $k \times k$ orthogonal matrix such that

$$B^T(q\Sigma_T + \Sigma_H)B = \text{diag}\{\eta_1, \dots, \eta_k\},$$

where $q = n_H/n_T$. Define

$$v = (v_1, \dots, v_k)^T = B(\mu_T - \mu_H),$$

and similarly define

$$\hat{v} = (\hat{v}_1, \dots, \hat{v}_k) = \hat{B}(\hat{\mu}_T - \hat{\mu}_H),$$

where

$$\hat{B}^T(q\hat{\Sigma}_T + \hat{\Sigma}_H)\hat{B} = \text{diag}\{\hat{\eta}_1, \dots, \hat{\eta}_k\},$$

and $\hat{\mu}_i$ and $\hat{\Sigma}_i$ are the sample mean and the sample covariance, respectively, for $i = T, H$.

Then, parameter γ can be rewritten as

$$\gamma = \sum_{i=1}^k v_i^2 + \lambda_1(\Sigma_T) - \lambda_1(\Sigma_H) - \in \max\{\sigma_0^2, \lambda_1(\Sigma_H)\}.$$

It is easily seen that $\hat{v}_i, i = 1, \dots, k$, are asymptotically independent and normally distributed as $N(\nu_i, \eta_i)$. Let $\hat{\eta}_i$ be the i th diagonal element of $\hat{B}^T(q\hat{\Sigma}_T + \hat{\Sigma}_H)\hat{B}$. Then, an asymptotic 95% confidence upper bound for v_i^2 is

$$\sum_{i=1}^k \hat{v}_i^2 + 2z_{0.05} \sqrt{\frac{\sum_{i=1}^k \hat{v}_i^2 \hat{\eta}_i}{n_H}},$$

where $z_{0.05}$ is the 95%th percentile of the standard normal distribution.

Let $l_{1,T}$ be the largest eigenvalue of $\hat{\Sigma}_T$. Then, an asymptotic 95% confidence upper bound for $\lambda_1(\Sigma_T)$ is^[5]

$$\frac{l_{1,T}}{1 - z_{0.05} \sqrt{2/n_T}}.$$

Similarly, an asymptotic 95% confidence lower bound for $\lambda_1(\Sigma_H)$ is

$$\frac{l_{1,H}}{1 + z_{0.05} \sqrt{2/n_H}}.$$

If $\lambda_1(\Sigma_H) \geq \sigma^2$, then γ in Eq. 3 reduces to

$$\gamma = \sum_{i=1}^k v_i^2 + \lambda_1(\Sigma_T) - (1 + \in)\lambda_1(\Sigma_H). \quad (5)$$

Since $\hat{v}_i$'s, $l_{1,T}$ and $l_{1,H}$ are independent, then using the ideas of Howe^[6] and Graybill and Wang^[7], we construct an approximate 95% confidence upper bound for γ as

$$\hat{\gamma}_{U,1} = \sum_{i=1}^k \hat{v}_i^2 + l_{1,T} - (1 + \in)l_{1,H} + \sqrt{\Delta_1}, \quad (6)$$

where

$$\Delta_1 = \frac{4z_{0.05}^2 \sum_{i=1}^k \hat{v}_i^2 \hat{\eta}_i}{n_H} + \left(\frac{l_{1,T}}{1 - z_{0.05} \sqrt{2/n_T}} - l_{1,T} \right)^2 + (1 + \in)^2 \left(\frac{l_{1,H}}{1 - z_{0.05} \sqrt{2/n_H}} - l_{1,H} \right)^2.$$

If $\lambda_1(\Sigma_H) < \sigma_0^2$, then γ in Eq. 3 reduces to

$$\gamma = \delta + \lambda_1(\Sigma_T) - \lambda_1(\Sigma_H) - \epsilon \sigma_0^2. \quad (7)$$

An approximate 95% confidence upper bound for γ is

$$\hat{\gamma}_{U,2} = \sum_{i=1}^k \hat{v}_i^2 + l_{1,T} - l_{1,H} - \epsilon \sigma_0^2 + \sqrt{\Delta_2}, \quad (8)$$

where

$$\Delta_2 = \frac{4z_{0.05}^2 \sum_{i=1}^k v_i^2 \hat{\eta}_i}{n_H} + \left(\frac{l_{1,T}}{1 - z_{0.05} \sqrt{2/n_T}} - l_{1,T} \right)^2 + \left(\frac{l_{1,H}}{1 - z_{0.05} \sqrt{2/n_H}} - l_{1,H} \right)^2.$$

For testing Eq. 2, it is equivalent to test

$$\gamma \leq 0, \text{ versus } H_1: \gamma < 0. \quad (9)$$

We propose the following testing rule: Reject H_0 if $l_{1,H} \geq \sigma_0^2$ and $\hat{\gamma}_{U,1} < 0$, or $l_{1,H} < \sigma_0^2$ and $\hat{\gamma}_{U,2} < 0$.

Specifically, we claim that the testing rule

$$\phi = I(\hat{\gamma}_{U,1} < 0, l_{1,H} \geq \sigma_0^2) + I(\hat{\gamma}_{U,2} < 0, l_{1,H} < \sigma_0^2) \quad (10)$$

has an approximate level of 0.05 for testing H_0 .

When the sample size is small, this test ϕ tends to be aggressive in rejecting the null hypothesis. We recommend replacing $z_{0.05}$ by $z_{0.025}$ in practice unless the sample size is very large.

Sample Size Determination

From the derivation of the test, we can show that if $\lambda_1(\Sigma_H) \geq \sigma_0^2$, as $n_H \rightarrow \infty$,

$$\sqrt{n_H}(\hat{\gamma} - \gamma) \rightarrow_d N\left(0, 4 \sum_{i=1}^k v_i^2 \eta_i^2 + 2q\lambda_1^2(\Sigma_T) + 2(1+\epsilon)^2 \lambda_1^2(\Sigma_H)\right),$$

as $n_H \rightarrow \infty$, and if $\lambda_1(\Sigma_H) < \sigma_0^2$,

$$\sqrt{n_H}(\hat{\gamma} - \gamma) \rightarrow_d N\left(0, 4 \sum_{i=1}^k v_i^2 \eta_i^2 + 2q\lambda_1^2(\Sigma_T) + 2\lambda_1^2(\Sigma_H)\right),$$

as $n_H \rightarrow \infty$.

Therefore, for any fixed alternative value $\gamma_* < 0$ in Eq. 9, to achieve a power of $1 - \beta$ while controlling the type one error rate as α , the sample size needed for the control group is

$$n_H = \left(z_\alpha + z_\beta\right)^2 \sigma^2 / \gamma_*^2,$$

where

$$\sigma^2 = 4 \sum_{i=1}^k v_i^2 \eta_i^2 + 2q\lambda_1^2(\Sigma_T) + 2[1 + \epsilon I(\lambda_1(\Sigma_H) \geq \sigma_0^2)] \lambda_1^2(\Sigma_H).$$

SIMULATION

In our simulation, we set $k=10$, and since γ depends on μ_T and μ_H only through their difference $\mu_T - \mu_H$, we assume

$$\mu_T = (a, ar, ar^2, \dots, ar^9), \quad \mu_H = (0, 0, 0, \dots, 0),$$

where $a \neq 0$, $r \geq 0$. For the covariance matrix, we set

$$\Sigma_T = \begin{pmatrix} \sigma_1 I_5 & 0 \\ 0 & \sigma_2 I_5 \end{pmatrix} \cdot R_T \cdot \begin{pmatrix} \sigma_1 I_5 & 0 \\ 0 & \sigma_2 I_5 \end{pmatrix},$$

where I_5 is a 5×5 identity matrix, σ_1 is the standard deviation of the first five components of X_T , σ_2 is the standard deviation of the last five components of X_T , and R_T is the 10×10 correlation matrix. Similarly, we set

$$\Sigma_H = \begin{pmatrix} \tau_1 I_5 & 0 \\ 0 & \tau_2 I_5 \end{pmatrix} \cdot R_H \cdot \begin{pmatrix} \tau_1 I_5 & 0 \\ 0 & \tau_2 I_5 \end{pmatrix},$$

where τ_1 is the standard deviation of the first five components of X_H , τ_2 is the standard deviation of the last five components of X_H , and R_H is the 10×10 correlation matrix.

For illustration, we choose $\epsilon=2.0$, $\sigma_0=0.5$. Two types of correlation patterns are considered: component symmetric (CS) correlation and the autoregressive of order 1 (AR(1)) correlation, where the parameters for R_T and R_H are ρ_T and ρ_H , respectively. All estimations are based on 10,000 simulation runs and $z_{0.025}$ is used in the test.

The simulated sizes of the test under CS and AR(1) correlations are summarized in Tables 1 and 2, respectively. The size is controlled in all the CS scenarios but slightly inflated in some AR(1) scenarios.

One possible reason is that the estimations of a 10×10 covariance matrix and its largest eigenvalue λ_1 are not accurate enough in these cases when the sample size is as small as 120.

The simulated powers of the test under CS and AR(1) correlations are summarized in Tables 3 and 4, respectively. A balance design, i.e., $n_T = n_H$, typically yields a higher power than the case where more healthy controls are used, i.e., $n_H > n_T$. The simulation indicates that for an effect size of $\gamma = -2.00$, a sample size of 120 in each group would be adequate to achieve 80% power.

DISCUSSION

In this article, we assume that the health profile has a multivariate normal distribution. When part or all the components of the health profile are not normally distributed, the proposed method will be valid asymptotically when $\min\{n_T, n_H\} \rightarrow \infty$.

In this article, we consider the case that k is moderately large. When k is extremely large, i.e., when $k \gg \max\{n_T, n_H\}$, the methods for sparse principal component analysis, such as those of Zou et al.^[8] or Johnstone and Lu,^[9] should be used to estimate the covariance matrices, and the corresponding 95% confidence upper bound could be constructed using the bootstrap method.

The dissimilarity index defined in this article measures the closeness between a profile of a treated subject and a file of a healthy control using both mean and variance information. However, we did not model the causal relationship among the k components $X_1, \dots, X_k$. Per TCM theory, an alternative model incorporating causal information could be considered. Future research is thus warranted.

The approach we adopt is a population bioequivalence approach. It is therefore most relevant when the main purpose is to establish the treatment effect of a TCM at the population level. It is of interest to develop methods based on individual bioequivalence. Specifically, let X_H and X_T be the health profiles from the *same* subject where the former is the profile when the subject is known in a healthy condition, whereas the latter is the one after the subject received TCM for his sickness. Let μ_i and Σ_i be the mean and covariance of the profile when the subject is at status $i=H,T$, respectively, and let Σ_{TH} be the covariance between X_T and X_H due to the same subject. Then, we could define an illness index as

$$\vartheta = \frac{(\mu_T - \mu_H)^T (\mu_T - \mu_H) + \lambda_1(\Sigma_T) - \lambda_1(\Sigma_H) - 2\lambda_1(\Sigma_{TH})}{\max\{\sigma_0^2, \lambda_1(\Sigma_H)\}}$$

and consider testing

$$H_0 : \vartheta \geq \varepsilon \text{ versus } H_1 : \vartheta < \varepsilon,$$

where $\varepsilon > 0$ is a known health limit. Here, rejecting H_1 implies the efficacy of the TCM. The derivation of the test is more involved and hence will be constructed in a separate paper.

Abstract

Translational Medicine: Concepts, Statistical Methods, and Related Issues This entry focuses on statistical methods commonly employed in translational medicine, which is a multi-disciplinary entity that bridges basic scientific research with clinical development.

INTRODUCTION

In early 2000, the U.S. Food and Drug Administration (FDA) kicked off *Critical Path Initiative* to assist the sponsors to identify possible causes of the scientific challenges underlying the medical product pipeline problems. The Critical Path Opportunities List released by the FDA on March 16, 2006, identified (i) better evaluation tools and (ii) streamlining clinical trials as the top two topic areas to bridge the gap between the quick pace of new biomedical discoveries and the slower pace at which those discoveries are currently developed into therapies. This has led to the consideration of the use of adaptive design methods in clinical development and the focus of translational medicine (or science/research), which attempt to not only to identify best clinical benefit of a drug product under investigation but also to increase the probability of success. Statistical methods for the use of adaptive trial designs in clinical development can be found in Chow and Chang^[1] and Chang.^[2] In this article, however, we will focus on statistical methods that are commonly employed in translational medicine.

Chow^[3] classified translational medicine into three areas, namely, translation in language, translation in information, and translation in (medical) technology. Translation in language is referred to possible lost in translation of informed consent form and/or case report forms in multinational clinical trials. Lost in translation is commonly encountered due not only to differences in language, but also differences in perception, culture, medical practices, and so forth. A typical approach for assessment of the possible lost in translation is to first translate the informed consent form and/or the case report forms by an experienced expert and then translate back by a different experienced but independent expert. The back-translated version is then compared with the original version for consistency. If the

back-translated version passes the test for consistency, then the back-translated version is validated through a small-scale pilot study before it is applied to the intended multinational clinical trial. Translation in information is referred to as bench-to-bedside in translational science/research, which is also known as translational medicine. Translation in technology includes biomarker development and translation in diagnostic procedures between traditional Chinese medicine and Western medicine. In this article, we will focus on statistical methods for translation in information and translation in technology. Note that in practice, translational medicine is often divided into two areas, namely, discovery translational medicine and clinical translational medicine. Discovery translational medicine is referred to biomarker development, bench-to-bedside, and animal model versus human model, while clinical translational medicine includes translation among study endpoints, translation in technology, and the generalization from a target patient population to another.

In the next section, statistical methods for biomarker development, especially for optimal variable screening in microarray analysis, are outlined. Also included in this section is a cross-validation method for model selection and validation. The section “Bench-to-Bedside” discusses the ideas of a one-way and two-way translation process in pharmaceutical/clinical development. Whether or not an established animal model is predictive of a human model is examined in the section “Animal Model Versus Human Model.” The section “Translation in Study Endpoints” summarizes translation among different study endpoints. Issues that are commonly encountered in translation in technology are described in the section “Bridging Studies.” Also included in this section is the generalization of results obtained from a target patient population to another similar but different target patient population. Some concluding remarks are provided in the last section of this article.

BIOMARKER DEVELOPMENT

A biomarker is a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic process, or pharmacologic responses to a therapeutic intervention. Biomarkers can be classified as classifier markers, prognostic markers, and predictive markers. A classifier marker usually does not change over the course of study and can be used to identify patient population who would benefit from the treatment from those do not. A typical example is a DNA marker for population selection in the enrichment process of clinical trials. A prognostic marker informs the clinical outcomes, which is independent of treatment. A predictive marker informs the treatment effect on the clinical endpoint, which could be population-specific. That is, a predictive marker could be predictive for population A but not population B. It should be noted that the correlation between biomarker and true endpoint constitutes a prognostic marker. However, correlation between biomarker and true endpoint does not constitute a predictive biomarker.

In clinical development, a biomarker could be used to select the right population, to identify the natural course of disease, for early detection of disease, and to help to develop personalized medicine. The utilization of biomarkers could lead to better target populations, detection of a large effect size with smaller sample size, and timely decision-making. As indicated in the FDA Critical Path Initiative Opportunity List, better evaluation tools call for biomarker qualification and standards. Statistical methods for early stage biomarker qualification include, but are not limited to, (i) distance-dependent K-nearest neighbors (DD-KNN), (ii) K means clustering, (iii) single/average/complete linkage clustering, and (iv) distance-dependent Jarvis-Patrick clustering. More information can be found at http://www.ncicrf.gov/human_studies.shtml.

In what follows, we will review statistical methods that are commonly used in biomarker development for optimal variable screening. The selected variables will then be used to establish a predictive model through a model selection/validation process.

Optimal Variable Screening

DNA microarrays have been used extensively in medicinal practice. Microarrays identify a set of candidate genes that are possibly related to a clinical outcome of a disease (in disease diagnoses) or a medical treatment. However, there are many more candidate genes than the number of available samples (the sample size) in almost all studies, which leads to an irregular statistical problem in disease diagnoses or treatment outcome prediction. Some available statistical methods deal with a single gene at a time,^[4] which clearly do not provide the best solution for polygenic diseases. In practice, a meta-analysis and/or combining several similar studies is often considered to increase sample

size. These approaches, however, may not be appropriate due to the fact that (i) the combined dataset may still be much too small, and (ii) there may be heteroscedasticity among the data from different studies. Alternatively, Shao and Chow^[5] propose an optimal variable screening approach for dealing with the situation where the number of variables (genes) is much larger than the sample size.

Let y be a clinical outcome of interest and x be a vector of p candidate genes that are possibly related to y . Shao and Chow^[5] simply considered inference on the population of y conditional on x and noted that their proposed method can be applied to the unconditional analysis (i.e., both y and x are random). Consider the following model:

$$y = \beta'x + \varepsilon, \quad (1)$$

where β is a p -dimensional vector and the distribution of ε is independent of x with $E(\varepsilon) = 0$ and $E(\varepsilon^2) = \sigma^2$. Under the model (1), assume that there is a positive integer p_0 (which does not depend on n) such that only p_0 components of β are nonzero. Furthermore, β is in the linear space generated by the rows of $X'X$ for sufficiently large n , where x is the $n \times p_n$ matrix whose i th row is x'_i . In addition, assume that there is a sequence $\{\xi_n\}$ of positive numbers such that $\xi_n \rightarrow \infty$ and $\lambda_{in} = b_i \xi_n$, where λ_{in} is the i th nonzero eigenvalue of $X'X$, $i = 1, \dots, n$ and $\{b_i\}$ is a sequence of bounded positive numbers. Note that in many problems, $\xi_n = n$. Furthermore, there exists a constant $c > 0$ such that $p_n/\xi_n^c \rightarrow 0$. For the estimation of β , Shao and Chow^[5] considered the following ridge regression estimator.

$$\hat{\beta} = (X'X + h_n I_{p_n})^{-1} X'Y, \quad (2)$$

where $Y = (y_1, \dots, y_n)'$, I_{p_n} is the identity matrix of order p_n and $h_n > 0$ is the ridge parameter. The bias and variance of $\hat{\beta}$ are given by

$$\text{bias}(\hat{\beta}) = E(\hat{\beta}) - \beta = -(h_n^{-1} X'X + I_{p_n})^{-1} \beta$$

and

$$\text{var}(\hat{\beta}) = \sigma^2 (X'X + h_n I_{p_n})^{-1} X'X (X'X + h_n I_{p_n})^{-1}$$

Let β_i and $\hat{\beta}_i$ be the i th component of β and $\hat{\beta}$, respectively. Under the assumptions as described earlier, we have $E(\hat{\beta}_i - \beta_i)^2 \rightarrow 0$ (i.e., $\hat{\beta}_i$ is consistent for β_i in mean squared error) if h_n is suitably chosen. Thus, we have

$$\text{var}(\hat{\beta}) = \frac{\sigma^2}{h_n} \left(\frac{X'X}{h_n} + I_{p_n} \right)^{-1} \frac{X'X}{h_n} \left(\frac{X'X}{h_n} + I_{p_n} \right)^{-1}. \quad (3)$$

Hence, $\text{var}(\hat{\beta}_i) \rightarrow 0$ for all i as long as $h_n \rightarrow \infty$. Note that the analysis of the bias of $\hat{\beta}_i$ is more complicated. Let Γ be an orthogonal matrix such that

$$\Gamma'X'X\Gamma = \begin{pmatrix} \Lambda_n & 0_{n \times (n-p_n)} \\ 0_{(p_n-n) \times n} & 0_{(p_n-n) \times (p_n-n)} \end{pmatrix},$$

where Λ_n is a diagonal matrix whose i th diagonal element is λ_{in} and $0_{l \times k}$ is the $l \times k$ matrix of 0's. Then, it follows that

$$\text{bias}(\hat{\beta}) = - \left[\Gamma \left(\frac{\Gamma'X'X\Gamma}{h_n} + I_{p_n} \right) \Gamma' \right]^{-1} \beta = -\Gamma A \Gamma' \beta, \quad (4)$$

where A is a $p_n \times p_n$ diagonal matrix whose first n diagonal elements are $h_n/h_n + \lambda_{in}, i = 1, \dots, n$, and the last diagonal elements are all equal to 1. Under the above mentioned assumptions, combining the results for variance and bias of $\hat{\beta}_i$, i.e., Eqs. (3) and (4), it can be shown that for all i

$$E(\hat{\beta}_i - \beta_i)^2 = \text{var}(\hat{\beta}_i) + [\text{bias}(\hat{\beta}_i)]^2 \rightarrow 0$$

if h_n is chosen so that $h_n \rightarrow \infty$ at a rate slower than ξ_n (e.g., $h_n = \xi_n^{2/3}$). Based on this result, Shao and Chow^[5] proposed the following optimal variable screening procedure:^[5]

Let $\{a_n\}$ be a sequence of positive numbers satisfying $a_n \rightarrow 0$. For each fixed n , we screen out the i th variable if and only if $|\hat{\beta}_i| \leq a_n$.

Note that, after screening, only variables associated with $|\hat{\beta}_i| > a_n$ are retained in the model as predictors. The idea behind this variable screening procedure is similar to that in the Lasso method.^[6] Under certain conditions, Shao and Chow^[5] showed that their proposed optimal variable screen method is consistent in the sense that the probability that all variables (genes) unrelated to y , which will be screened out, and all variables (genes) related to y , which will be retained is 1 as n tends to infinity.

Model Selection and Validation

Suppose that n data points are available for selecting a model from a class of models. Several methods for model selection are available in the literature. These methods include, but are not limited to, Akaike information criterion (AIC),^[7,8] the C_p ,^[9] and the jackknife and the bootstrap.^[10] These methods, however, are not asymptotically consistent in the sense that the probability of selecting the model with the best predictive ability does not converge to 1 as the total number of observations $n \rightarrow \infty$. Alternatively, Shao^[11] proposed a method for model selection and validation using the method of cross-validation. The idea of cross-validation is to split the dataset into two parts. The first part contains n_c data points which will be used for fitting a model (model construction), whereas the second part contains $n_v = n - n_c$ data points that are reserved for assessing the predictive ability of the model (model validation). It

should be noted that all of the $n = n_c + n_v$ data, not just n_v are used for model validation. Shao^[11] showed that all of the methods of AIC, C_p , Jackknife and bootstrap are asymptotically equivalent to the cross-validation with $n_v = 1$, denoted by CV(1), although they share the same deficiency of inconsistency. Shao^[11] indicated that the inconsistency of the leave-one-out cross-validation can be rectified by using leave- n_v -out cross-validation with n_v satisfying $n_v/n \rightarrow 1$ as $n \rightarrow \infty$.

In addition to the cross-validation with $n_v = 1$, denoted by CV(1), Shao^[11] also considered the other two cross-validation methods, namely, a Monte Carlo cross-validation with $n_v (n_v \neq 1)$, denoted by MCCV(n_v), and an analytic approximate CV(n_v), denoted by APCV(n_v). MCCV(n_v) is a simple and easy method utilizing the method of Monte Carlo by randomly drawing (with or without replacement) a collection $\mathfrak{R}$ of b subsets of $\{1, \dots, n\}$ that have size n_v and select a model by minimizing

$$\hat{\Gamma}_{\alpha, n} = \frac{1}{n_v b} \sum_{s \in \mathfrak{R}} \|y_s - \hat{y}_{\alpha, s^c}\|^2$$

On the other hand, APCV(n_v) selects the optimal model based on the asymptotic leading term of balance incomplete CV(n_v), which treats each subset as a block and each i as a treatment. Shao^[11] compared these three cross-validation methods through a simulation study under the following model with five variables with $n = 40$:

$$y_i = \beta_1 x_{1i} + \beta_2 x_{2i} + \beta_3 x_{3i} + \beta_4 x_{4i} + \beta_5 x_{5i} + e_i,$$

where are i.i.d. from $N(0,1)$, x_{ki} is the i th value of the k th prediction variable x_k , $x_{1i} = 1$, and the values of x_{ki} , $k = 2, \dots, 5$, $i = 1, \dots, 40$, are taken from an example in Gunst and Mason^[12]. Note that there are 31 possible models, and each model was denoted by a subset of $\{1, \dots, 5\}$ that contains the indices of the variable x_k in the model. Shao^[11] indicated that MCCV(n_v) has the best performance among the three methods under study except for the case where the largest model is the optimal model. APCV(n_v) is slightly better than the CV(1) in all cases. CV(1) tends to select unnecessarily large models. The probability of selecting the optimal model by using the CV(1) could be very low (e.g., less than 0.5).

Remarks

In practice, it is suggested that the optimal variable screening method proposed by Shao and Chow^[5] be applied to select a few relevant variables say 5–10 variables. Then, apply the cross-validation method to select the optimal model based on linear model selection (Shao, 1993) or non-linear model selection.^[13] The selected model can then be validated based on the cross-validation methods as described in the previous subsection.

BENCH-TO-BEDSIDE

Pizzo^[14] defines translational medicine as *bench-to-bedside* research wherein a basic laboratory discovery becomes applicable to the diagnosis, treatment, or prevention of a specific disease and is brought forth by either a physician-scientist who works at the interface between the research laboratory and patient care or by a team of basic and clinical science investigators. Thus, translational medicine is referred to the translation of basic research discoveries into clinical applications. More specifically, translational medicine is to take the discoveries from basic research to a patient and measures an endpoint in a patient. Most recently, scientists are increasingly aware that this bench-to-bedside approach to translational research is a two-way street. Basic scientists provide clinicians with new tools for use in patients and for assessment of their impact, and clinical researchers make novel observations about the nature and progression of disease that often stimulate basic investigations. As indicated by Pizzo,^[14] translational medicine can also have a much broader definition, referring to the development and application of new technologies, biomedical devices, and therapies in patient-driven environments, such as clinical trials, where the emphasis is on early patient testing and evaluation. Thus, translational medicine also includes epidemiological and health-outcomes research and behavioral studies that can be brought to the bedside or ambulatory setting.

Mankoff et al.^[15] pointed out that there are three major obstacles to effective translational medicine in practice. The first is the challenge of translating basic science discoveries into clinical studies. The second hurdle is the translation of clinical studies into medical practice and health care policy. A third obstacle to effective translational medicine is philosophical. It may be a mistake to think that basic science (without observations from the clinic and without epidemiological findings of possible associations between different diseases) will efficiently produce the novel therapies for human testing. Pilot studies such as non-human and non-clinical studies are often used to transition therapies developed using animal models to a clinical setting. Statistical process plays an important role in translational medicine. In particular, we define a statistical process of translational medicine as a translational process for (i) determining association between some independent parameters observed in basic research discoveries and dependent variable observed from clinical application, (ii) establishing a predictive model between the independent parameters and the dependent response variable, and (iii) validating the established predictive model. For example, in animal studies, the independent variables may include *invitro* assay results, pharmacological activities such as pharmacokinetics and pharmacodynamics, and dose toxicities and the dependent variable could be a clinical outcome (e.g., a safety parameter). Statistical methods related

to (i) and (ii) are well documented in statistical literature. However, research effort is needed to develop appropriate criteria to assess the accuracy of a translation process.

If the information observed in basic research discoveries is translated to clinical practice, it is usually referred to as a one-way translation process. However, as indicated by Pizzo,^[14] the translational process should be a two-way translation, where information obtained in clinical study could also be translated back to basic research discoveries. Tse^[16] described the statistical process of how to validate a translational process, either one-way or two-way, based on some probability-based criteria. Furthermore, a measure to assess the degree of lost in translation was also proposed.

The following sections describe basic statistical concepts and statistical tests for one-way and two-way translation between basic research discoveries and clinical outcome under a well-established and validated predictive model. In particular, two different criteria and the corresponding statistical tests for one-way translation are discussed. Furthermore, a procedure for the evaluation of two-way translation and the statistical assessment of the lost in translation is briefly discussed.

One-Way Translation

Let x and y be the observed values from basic research discoveries and clinical application, respectively. In practice, it is important to ensure that the translational process is accurate and reliable with some statistical assurance. One of the statistical criteria is to examine the closeness between the observed response y and the predicted response $\hat{y}$ via a translational process. To study this, we will first study the association between x and y and build up a model. Then, we will validate the model based on some criteria. For simplicity, we assume that x and y can be described by the following linear model

$$y = \beta_0 + \beta_1 x + \varepsilon, \quad (5)$$

where ε follows a normal distribution with mean 0 and variance σ_e^2 .

Suppose that n pairs of observations $(x_1, y_1), \dots, (x_n, y_n)$ are observed in a translation process. To define notation, let $X^T = \begin{pmatrix} 1 & 1 & \dots & 1 \\ x_1 & x_2 & \dots & x_n \end{pmatrix}$ and $Y^T = (y_1 \ y_2 \ \dots \ y_n)$.

Then, under model (1), the maximum likelihood estimates (MLE) of the parameters β_0 and β_1 are given as

$$\begin{pmatrix} \hat{\beta}_0 \\ \hat{\beta}_1 \end{pmatrix} = (X^T X)^{-1} X^T Y \text{ with } \text{var} \begin{pmatrix} \hat{\beta}_0 \\ \hat{\beta}_1 \end{pmatrix} = (X^T X)^{-1} \sigma_e^2. \text{ Thus, the}$$

following relationship

$$\hat{y} = \hat{\beta}_0 + \hat{\beta}_1 x \quad (6)$$

can be established between x and y , the observed values from basic research discoveries and clinical application respectively.

Given x_i from Eq. (6), the corresponding fitted value $\hat{y}_i$ is $\hat{y}_i = \hat{\beta}_0 + \hat{\beta}_1 x_i$. Furthermore, the corresponding MLE of σ_e^2 is $\hat{\sigma}_e^2 = \frac{1}{n} \sum_{i=1}^n (y_i - \hat{y}_i)^2 = \frac{n-2}{n}$ MSE, where MSE is the mean squared errors of the fitted model.

For a given $x = x_0$, suppose that the corresponding observed value is given by y ; using (6), the corresponding fitted value is $\hat{y} = \hat{\beta}_0 + \hat{\beta}_1 x_0$. Note that $E(\hat{y}) = \beta_0 + \beta_1 x_0 = \mu_0$ and

$$\text{Var}(\hat{y}) = (1 \quad x_0) (X^T X)^{-1} \begin{pmatrix} 1 \\ x_0 \end{pmatrix} \sigma_e^2 = c \sigma_e^2,$$

where $c = (1 \quad x_0) (X^T X)^{-1} \begin{pmatrix} 1 \\ x_0 \end{pmatrix}$. Furthermore, $\hat{y}$ is normally distributed with mean μ_0 and variance $c \sigma_e^2$, i.e., $\hat{y} \sim N(\mu_0, c \sigma_e^2)$.

Measures of Closeness

We may validate the translation model by considering how close an observed y and its predicted value obtained based on the fitted regression model given by (6). To assess the closeness, we propose the following two measures, which are based either on the absolute difference or the relative difference between y and $\hat{y}$:

$$\text{Criterion I.} \quad p_1 = P\{|y - \hat{y}| < \delta\},$$

$$\text{Criterion II.} \quad p_2 = P\left\{\left|\frac{y - \hat{y}}{y}\right| < \delta\right\}.$$

In other words, it is desirable to have a high probability that the difference or the relative difference between y and $\hat{y}$, given by p_1 and p_2 respectively, is less than a clinically or scientifically meaningful difference δ . Then, for either $i = 1$ or 2 , it is of interest to test the following hypotheses

$$H_0: p_i \leq p_0 \quad \text{vs.} \quad H_a: p_i > p_0, \quad (7)$$

where p_0 is some pre-specified constant. If the conclusion is to reject H_0 in favor of H_a , this would imply that the established model is considered validated. The steps in carrying out the test of hypothesis corresponding to the two criteria are outlined in the following section.

Measure of closeness based on absolute difference It is easy to show that $p_1 = \Phi(\delta/\sqrt{(1+c)\sigma_e^2}) - \Phi(-\delta/\sqrt{(1+c)\sigma_e^2})$, where Φ is the cumulative density function of a standard normal distribution. Thus, the MLE of p_1 is given by $\hat{p}_1 = \Phi(\delta/\sqrt{(1+c)\hat{\sigma}_e^2}) - \Phi(-\delta/\sqrt{(1+c)\hat{\sigma}_e^2})$. Define $V_1 = (2\delta^2/(1+c)n\sigma_e^2) \phi^2(\delta/\sqrt{(1+c)\hat{\sigma}_e^2})$, where $\phi(z)$ is the probability density function of a standard normal distribution. For a sufficiently large sample size n , using Slutsky Theorem, $\hat{p}_1 - p_0/\sqrt{V_1}$ can be approximated by a standard

normal distribution. Based on these results, for the testing of the hypotheses,

$$H_0: p_1 \leq p_0 \quad \text{vs.} \quad H_a: p_1 > p_0,$$

H_0 is rejected if $\hat{p}_1 - p_0/\sqrt{V_1} > z_{1-\alpha}$, where $z_{1-\alpha}$ is the $100(1-\alpha)^{\text{th}}$ percentile of a standard normal distribution.

Measure of closeness based on the absolute relative difference Recall that the measure of closeness based on the absolute relative difference is given by $p_2 = P\{|y - \hat{y}|/y < \delta\}$, where p_2 is determined by a non-central F distribution and can be approximated by a central F distribution. In particular, it can be shown that $p_2 \approx P\{((1-\delta)^2/c)(1+\lambda_2/1+\lambda_1 < F_{v,v'} < (1+\lambda_2/1+\lambda_1)(1+\delta)^2/c\}$, where $\lambda_1 = \mu_0^2/c\sigma_e^2$ and $\lambda_2 = \mu_0^2/c\sigma_e^2$ and $f_{v,v'}$ is a central F distribution with degrees of freedom $v = (v_1 + \lambda_1)2/v_1 + 2\lambda_1 = (1 + \mu_0^2/c\sigma_e^2)^2 / (1 + 2\mu_0^2/c\sigma_e^2)$ and $v' = (v_1 + \lambda_1)^2/v_2 + 2\lambda_2 = (1 + \mu_0^2/c\sigma_e^2)^2 / (1 + 2\mu_0^2/c\sigma_e^2)$. Thus, p_2 can be estimated by

$$\begin{aligned} \hat{p}_2 &= P\left\{\frac{(1-\delta)^2}{c} \frac{1+\hat{\lambda}_2}{1+\hat{\lambda}_1} < F_{\hat{v},\hat{v}'} < \frac{1+\hat{\lambda}_2}{1+\hat{\lambda}_1} \frac{(1+\delta)^2}{c}\right\} \\ &= P\{u_1 < F_{\hat{v},\hat{v}'} < u_2\}; \end{aligned}$$

where $u_1 = (1 + \hat{\lambda}_2/c(1 + \hat{\lambda}_1))(1 - \delta)^2$, $u_2 = (1 + \hat{\lambda}_2/c(1 + \hat{\lambda}_1))x(1 + \delta)^2$ and $(\hat{\lambda}_1, \hat{\lambda}_2, \hat{v}, \hat{v}')$ are the corresponding MLE of $(\lambda_1, \lambda_2, v, v')$. Furthermore, denote $\Delta = \left(\frac{\partial \hat{p}_2}{\partial \hat{\beta}_0}, \frac{\partial \hat{p}_2}{\partial \hat{\beta}_1}, \frac{\partial \hat{p}_2}{\partial \hat{\sigma}_e^2}\right)$, where

$$\begin{aligned} \frac{\partial \hat{p}_2}{\partial \hat{\beta}_0} &= \frac{2(c-1)\hat{\mu}_0}{c^2\hat{\sigma}_e^2(1+\hat{\lambda}_1)^2} \left[(1+\delta)^2 f_{\hat{v},\hat{v}'}(u_2) - (1-\delta)^2 f_{\hat{v},\hat{v}'}(u_1) \right] \\ &\quad + \frac{4\hat{\lambda}_1^2(1+\hat{\lambda}_1)}{\hat{\mu}_0(1+2\hat{\lambda}_1)^2} \int_{u_1}^{u_2} \frac{\partial f_{\hat{v},\hat{v}'}(x)}{\partial \hat{v}} dx \\ &\quad + \frac{4\hat{\lambda}_2^2(1+\hat{\lambda}_2)}{\hat{\mu}_0(1+2\hat{\lambda}_2)^2} \int_{u_1}^{u_2} \frac{\partial f_{\hat{v},\hat{v}'}(x)}{\partial \hat{v}'} dx, \\ \frac{\partial \hat{p}_2}{\partial \hat{\beta}_1} &= x \frac{\partial \hat{p}_2}{\partial \hat{\beta}_0}; \end{aligned}$$

and

$$\begin{aligned} \frac{\partial \hat{p}_2}{\partial \hat{\sigma}_e^2} &= \frac{2(c-1)\hat{\mu}_0}{c^2\hat{\sigma}_e^2(1+\hat{\lambda}_1)^2} \left[(1+\delta)^2 f_{\hat{v},\hat{v}'}(u_2) - (1-\delta)^2 f_{\hat{v},\hat{v}'}(u_1) \right] \\ &\quad - \frac{2\hat{\lambda}_1^2(1+\hat{\lambda}_1)}{\hat{\sigma}_e^2(1+2\hat{\lambda}_1)^2} \int_{u_1}^{u_2} \frac{\partial f_{\hat{v},\hat{v}'}(x)}{\partial \hat{v}} dx \\ &\quad - \frac{2\hat{\lambda}_2^2(1+\hat{\lambda}_2)}{\hat{\sigma}_e^2(1+2\hat{\lambda}_2)^2} \int_{u_1}^{u_2} \frac{\partial f_{\hat{v},\hat{v}'}(x)}{\partial \hat{v}'} dx; \end{aligned}$$

with

$$\partial f_{\hat{v}, \hat{v}'}(x) / \partial \hat{v} = 1/2 \left(f_{\hat{v}, \hat{v}'}(x) \left[(\log \Gamma(\hat{v} + \hat{v}'))^{(1)} - (\log \Gamma(\hat{v}))^{(1)} + \log(\hat{v}x / \hat{v}x + \hat{v}') + \hat{v}'(1-x) / \hat{v}x + \hat{v}' \right] \right),$$

$$\partial f_{\hat{v}, \hat{v}'}(x) / \partial \hat{v}' = 1/2 \left(f_{\hat{v}, \hat{v}'}(x) \left[(\log \Gamma(\hat{v} + \hat{v}'))^{(1)} - (\log \Gamma(\hat{v}'))^{(1)} + \log(\hat{v}' / \hat{v}x + \hat{v}') + \hat{v}(1-x) / \hat{v}x + \hat{v}' \right] \right)$$

and $(\log \Gamma(s))^{(1)}$ is the first order derivative of the natural logarithm of the gamma function with respect to s .

For a sufficiently large sample size, $\hat{p}_2$ can be approximated by a normal distribution with mean p_2 and variance V_2 , where

$$V_2 = \Delta \begin{pmatrix} (X^T X)^{-1} \hat{\sigma}_e^2 & 0 \\ 0' & \frac{2\hat{\sigma}_e^4}{n-2} \end{pmatrix} \Delta^T.$$

Thus, the hypotheses given in (7) for one-way translation based on the probability of relative difference can be tested. In particular, H_0 is rejected if

$$Z = \frac{\hat{p}_2 - p_0}{\sqrt{\hat{V}_2}} > z_{1-\alpha},$$

where $z_{1-\alpha}$ is the $100(1-\alpha)^{\text{th}}$ percentile of a standard normal distribution. Note that $\hat{V}_2$ is an estimate of $\text{var}(\hat{p}_2)$ and can be evaluated simply by replacing the parameters with their corresponding estimates of the parameters.

An Example

For the two measures proposed in the above section, p_1 is based on the absolute difference between y and $\hat{y}$. Given α , p_0 and the selected observation (x_0, y_0) , the hypothesis $H_0: p_1 > p_0$ is rejected in favor of $H_a: p_1 > p_0$ when $Z = \hat{p}_1 - p_0 / \sqrt{\hat{V}_1} > z_{1-\alpha}$. Equivalently, H_0 is rejected when $(\hat{p}_1 - p_0 - z_{1-\alpha} \sqrt{\hat{V}_1}) > 0$. Note that the value of $\hat{p}_1$ depends on the value of δ and it can be shown that $(\hat{p}_1 - p_0 - z_{1-\alpha} \sqrt{\hat{V}_1})$ is an increasing function of δ over $(0, \infty)$. Thus, $(\hat{p}_1 - p_0 - z_{1-\alpha} \sqrt{\hat{V}_1}) > 0$ if and only if $\delta > \delta_0$. Thus, the hypothesis H_0 can be rejected based on δ_0 instead of $\hat{p}_1$ as long as we can find the value of δ_0 for the given x_0 . On the other hand, from a practical point of view, p_2 is more intuitive to understand because it is based on the relative difference, which is equivalent to measure the percentage difference relative to the observed y and δ can be viewed as the upper bound of the percentage error.

For illustration purpose, suppose that the following data are observed in a translational study, where x is a given dose level and y is the associated toxicity measure:

x	0.9	1.1	1.3	1.5	2.2	2.0	3.1	4.0	4.9	5.6
y	0.9	0.8	1.9	2.1	2.3	4.1	5.6	6.5	8.8	9.2

When this set of data is fitted to model (1), the estimates of the model parameters are given by $\hat{\beta}_0 = -0.704$, $\hat{\beta}_1 = 1.851$, $\hat{\sigma}^2 = 0.431$. Thus, based on the fitted results, given $x = x_0$, the proposed translation model is given by $\hat{y} = -0.704 + 1.851x_0$.

In this study, choose $\alpha = 0.05$ and $p_0 = 0.8$. In particular, two dose levels $x_0 = 1.0$ and 5.2 are considered. Based on the study, the corresponding toxicity measures y_0 are 1.2 and 9.0 respectively. However, based on the translation model, the predicted toxicity measures are 1.147 and 8.921 , respectively. In the following, the validity of the translation model is assessed by the two proposed closeness measures p_1 and p_2 , respectively. Without loss of generality, choose $\alpha = 0.05$ and $p_0 = 0.8$.

Case 1: Testing of $H_0: p_1 \leq p_0$ vs. $H_a: p_1 > p_0$

Using the above results, for $x_0 = 1.0$, δ is 1.112 , since $|y_0 - \hat{y}| = |1.2 - 1.147| = 0.053$, which is less than $\delta = 1.112$, therefore H_0 is rejected. Similarly, for $x_0 = 5.2$, the corresponding δ is 1.178 , then $|y_0 - \hat{y}| = |9.0 - 8.921| = 0.079$, which is again smaller than $\delta = 1.178$, thus H_0 is rejected.

Case 2: Testing of $H_0: p_2 \leq p_0$ vs. $H_a: p_2 > p_0$

Suppose that $\delta = 1$, for the given two values of x , estimates of p_2 and the corresponding values of the test statistic Z are given in the following table.

x_0	y_0	$\hat{y}$	$\hat{p}_2$	Z	
1.0	1.2	1.147	0.870	1.183	Do not reject H_0
5.2	9.0	8.921	0.809	1.164	Do not reject H_0

Two-Way Translation

Validation of a Two-Way Translational Process

The translational process described in the section “One-Way Translation” is usually referred to as a *one-way translation* in translational medicine. That is, the information observed at basic research discoveries is translated to clinic. In other words, we can exchange x and y in Eq. (5)

$$x = \gamma_0 + \gamma_1 y + \varepsilon \quad (8)$$

and come up with another predictive model $\hat{x} = \hat{\gamma}_0 + \hat{\gamma}_1 y$.

Following the similar ideas, using either one of the measures p_i , the validation of a two-way translational process can be summarized by the following steps:

Step 1: For a given set of data (x, y) , established a predictive model, say, $y = f(x)$.

- Step 2: Select the bound δ_{yi} for the difference between y and $\hat{y}$. Evaluate $\hat{p}_{yi} = P\{|y - \hat{y}| < \delta_{yi}\}$. Assess the one-way closeness between y and $\hat{y}$ by testing the hypotheses (7). Proceed to the next step if the one-way translation process is validated.
- Step 3: Consider x as the dependent variable and y as the independent variable. Set up the regression model. Predict x at the selected observation y_0 , denoted by $\hat{x}$, based on the established model between x and y (i.e., $x = g(y)$), i.e., $\hat{x} = g(y) = \hat{\gamma}_0 + \hat{\gamma}_1 y$.
- Step 4: Select the bound δ_{xi} for the difference between x and $\hat{x}$. Evaluate the closeness between x and $\hat{x}$ based on a test for the following hypotheses

$$H_0: p_i \leq p_0 \quad \text{vs.} \quad H_1: p_i > p_0$$

where

$$p_i = P\left\{\left|\frac{y - \hat{y}}{y}\right| < \delta_{yi} \quad \text{and} \quad \left|\frac{x - \hat{x}}{x}\right| < \delta_{xi}\right\}$$

The above test can be referred to as a test for two-way translation. If, in Step 4, H_0 is rejected in favor of H_1 , this would imply that there is a two-way translation between x and y (i.e., the established predictive model is validated). However, the evaluation of p involved the joint distribution of $x - \hat{x}/x$ and $y - \hat{y}/y$. An exact expression is not readily available. Thus, an alternative approach is to modify Step 4 of the above procedure and proceed with a conditional approach instead. In particular,

Step 4 (modified): Select the bound δ_{xi} for the difference between x and $\hat{x}$. Evaluate the closeness between x and $\hat{x}$ based on a test for the following hypotheses,

$$H_0: p_{xi} \leq p_0 \quad \text{vs.} \quad H_a: p_{xi} > p_0 \quad (9)$$

where $p_{xi} = \{ |x - \hat{x}| < \delta_{xi} \}$.

Note that the evaluation of p_{xi} is much easier and can be computed in similarly by interchanging the role of x and y for the results given in section “Measures of Closeness.”

An Example (Continued)

Using the data set given in section “An Example,” we set up the regression model $x = \gamma_0 + \gamma_1 y + \varepsilon$ with y as the independent variable and x as the dependent variable. The estimates of the model parameters are $\hat{\gamma}_0 = 0.468$, $\hat{\gamma}_1 = 0.519$, and $\hat{\sigma}^2 = 0.121$. Based on this model, for the same α and p_0 , given $(x_0, y_0) = (1.0, 1.2)$ and $(5.2, 9.0)$, the fitted values are given by $\hat{x} = 0.468 + 0.519y_0$.

Case 1: Testing of $H_0: p_{x1} \leq p_0$ vs. $H_a: p_{x1} > p_0$

Using the above results, for $y_0 = 1.2$, δ is 0.587, since $|x_0 - \hat{x}| = |1.0 - 1.09| = 0.09$, which is less than $\delta_x = 0.587$, therefore H_0 is rejected. Similarly, for $y_0 = 9.0$, the corresponding δ is 0.624, then $|x_0 - \hat{x}| = |5.2 - 5.139| = 0.061$, which is again smaller than $\delta = 0.624$, thus H_0 is rejected.

Case 2: Testing of $H_0: p_{x2} \leq p_0$ vs. $H_a: p_{x2} > p_0$

Suppose that $\delta = 1$, for the given two values of y , estimates of p_{x2} and the corresponding values of the test statistic Z are given in the following table.

x_0	y_0	$\hat{x}_0$	$\hat{p}_{x2}$	Z	
1.0	1.2	1.090	0.809	1.300	Do not reject H_0
5.2	9.0	5.139	0.845	16.53	Do not reject H_0

Lost in Translation

It can be noted that δ_y and δ_x can be viewed as the maximum bias (or possible lost in translation) from the one-way translation (e.g., from basic research discovery to clinic) and from the other way of translation (e.g., from clinic to basic research discovery), respectively. If δ_y and δ_x given in steps 2 and 4 of section “One-Way Translation” are close to 0 with a relatively high probability, then we conclude that the information from the basic research discoveries (clinic) is fully translated to the clinic (basic research discoveries). Thus, one may consider the following parameter to measure the degree of lost in translation

$$\zeta = 1 - p_{xy} p_{yx},$$

where p_{xy} is the measure of closeness from x to y and p_{yx} is the measure of closeness from y to x . When $\zeta \approx 0$, we consider that there is no lost in translation. Overall lost in translation could be significant even lost in translation from the one-way translation is negligible. To illustrate, if there is a 10% lost in translation in one-way translation and 20% lost in translation in the other way, there would be an up to 28% lost in translation. In practice, an estimate of ζ can be obtained for a given set of data (x, y) . In particular, $\hat{\zeta} = 1 - p_{xy} p_{yx}$.

As an illustration, consider the example discussed in the section “An Example (Continued).” Suppose that the measure of closeness based on relative difference is used, given $(x_0, y_0) = (1.0, 1.2)$ and $(5.2, 9.0)$, the corresponding lost in translation for the two-way translation with $\delta = 1$ is tabulated in the following table:

x_0	y_0	$\hat{y}$	$\hat{p}_{xy}$	$\hat{x}$	$\hat{p}_{yx}$	$\hat{\zeta}$
1.0	1.2	1.147	0.870	1.090	0.809	0.296
5.2	9.0	8.921	0.809	5.139	0.845	0.316

ANIMAL MODEL VERSUS HUMAN MODEL

In translational medicine, a commonly asked question is that whether an animal model is predictive of a human model. To address this question, we may assess the similarity between an animal model (population) and a human model (population). For this purpose, we first establish an animal model to bridge the basic research discovery (x) and clinic (y). For example, consider a one-way translation process where $y = \beta_0 + \beta_1 x + \varepsilon$. Let $\hat{y} = \hat{\beta}_0 + \hat{\beta}_1 x$ be the predictive model obtained from the one-way translation based on data from an animal population. Thus, for a given x_0 , $\hat{y}_0 = \hat{\beta}_0 + \hat{\beta}_1 x_0$ follows a distribution with mean μ_y and σ_y^2 . Under the predictive model $\hat{y} = \hat{\beta}_0 + \hat{\beta}_1 x$, denote by (μ_y, σ_y) the target population. Assume that the predictive model works for the target population. Thus, for an animal population, $\mu_y = \mu_{\text{animal}}$ and $\sigma_y = \sigma_{\text{animal}}$, while for a human population, $\mu_y = \mu_{\text{human}}$ and $\sigma_y = \sigma_{\text{human}}$. Assuming that the linear predictive model can be applied to both animal population and human population, we can link the animal and human model by the following

$$\mu_{\text{human}} = \mu_{\text{animal}} + \varepsilon,$$

and

$$\sigma_{\text{human}} = C\sigma_{\text{animal}}.$$

In other words, we expect there are differences in population mean and population standard deviation under the predictive model due to possible differences in response between animal and human. As a result, the effect size adjusted for standard deviation under the human population can be obtained as follows:

$$\left| \frac{\mu_{\text{human}}}{\sigma_{\text{human}}} \right| = \left| \frac{\mu_{\text{animal}} + \varepsilon}{C\sigma_{\text{animal}}} \right| = |\Delta| \left| \frac{\mu_{\text{animal}}}{\sigma_{\text{animal}}} \right|$$

where $\Delta = (1 + \varepsilon/\mu_{\text{animal}})/C$. Chow et al.^[17] refer to Δ as a sensitivity index when changing from a target population to another. As can be seen, the effect size under the human population is inflated (or reduced) by the factor of Δ . If $\varepsilon = 0$ and $C = 1$, we then claim that there is no difference between the animal population and the human population. Thus, the animal model is predictive of the human model. Note that the shift and scale parameters (i.e., ε and C) can be estimated by

$$\hat{\varepsilon} = \hat{\mu}_{\text{human}} - \hat{\mu}_{\text{animal}}$$

and

$$\hat{C} = \frac{\hat{\sigma}_{\text{human}}}{\hat{\sigma}_{\text{animal}}},$$

respectively, in which $(\hat{\mu}_{\text{animal}}, \hat{\sigma}_{\text{animal}})$ and $(\hat{\mu}_{\text{human}}, \hat{\sigma}_{\text{human}})$ are estimates of $(\mu_{\text{animal}}, \sigma_{\text{animal}})$ and $(\mu_{\text{human}}, \sigma_{\text{human}})$, respectively. Thus, the sensitivity index can be assessed as follows:

$$\hat{\Delta} = (1 + \hat{\varepsilon}/\mu_{\text{human}})/\hat{C}.$$

In practice, there may be a shift in population mean (i.e., ε) and/or in population standard deviation (i.e., C), Chow et al.^[18] indicated that shifts in population mean and population standard deviation can be classified into the following four cases where (i) both ε and C are fixed, (ii) ε is random and C is fixed, (iii) ε is fixed and C is random, and (iv) both ε and C are random. For the case where both ε and C are fixed, (v) can be used for estimation of.^[18] Chow et al.^[18] derived statistical inference of Δ for the case where ε is random and C is fixed by assuming that y conditional on μ follows a normal distribution $N(\mu, \sigma^2)$. That is,

$$y|_{\mu=\mu_{\text{human}}} \sim N(\mu, \sigma^2),$$

where μ is distributed as $N(\mu_{\mu}, \sigma_{\mu}^2)$ and σ, μ_{μ} , and σ_{μ} , are some unknown constants. It can be verified that y follows a mixed normal distribution with mean μ_{μ} and variance $\sigma^2 + \sigma_{\mu}^2$. That is, $y \sim N(\mu_{\mu}, \sigma^2 + \sigma_{\mu}^2)$. As a result, the sensitivity index can be assessed based on data collected from both animal and human population under the predictive model.

Note that for other cases where C is random, the above method can also be derived similarly. The assessment of sensitivity index can be used to adjust the treatment effect to be detected under a human model when applying an animal model to a human model, especially when there is a significant or major shift between an animal population and the human population. In practice, it is of interest to assess the impact of the sensitivity index on both lost in translation and the probability of success. This, however, requires further research.

TRANSLATION IN STUDY ENDPOINTS

In clinical trials, it is not uncommon that a study is powered based on expected absolute change from baseline of a primary study endpoint, but the collected data are analyzed based on relative change from baseline (e.g., percent change from baseline) of the primary study endpoint. In many cases, the collected data are analyzed based on the percentage of patients who show some improvement (i.e., responder analysis). The definition of a responder could be based on either absolute change from baseline or relative change from baseline of the primary study endpoint. It is very controversial in terms of the interpretation of the analysis results, especially when a significant result is observed based on a study endpoint (e.g., absolute change from baseline, relative change from baseline, or the responder analysis) but not on the other study endpoint (e.g., absolute change from baseline, relative change from baseline, or responder analysis). In practice, it is then of interest to explore how an observed significant difference of a study endpoint (e.g., absolute change from baseline,

relative change from baseline, or responder's analysis) can be translated to that of the other study endpoint (e.g., absolute change from baseline, relative change from baseline, or responder's analysis).

Power Analysis and Sample Size Calculation

An immediate impact on the assessment of treatment effect based on different study endpoints is the power analysis for sample size calculation. For example, sample size required in order to achieve the desired power based on the absolute change could be very different from that obtained based on the percent change, or the percentage of patients who show an improvement based on the absolute change or relative change at α level of significance. Let w_{1i} and w_{2i} be the measurements of the i -th subject before and after the treatment, respectively. For example, assume that w_{1i} are lognormal distributed, i.e., $\log w_{1i} \sim N(\mu_1, \sigma^2)$. Let $w_{2i} \equiv w_{1i}(\tilde{w}_{1i} + 1)$, where $\log \tilde{w}_{1i} \sim N(\mu_2, \sigma^2)$ and w_{1i} , $\tilde{w}_{1i}$ are independent for $1 \leq i, j \leq n$. It easily follows that $\log(w_{2i} - w_{1i}) \sim N(\mu_1 + \mu_2, 2\sigma^2)$ and $\log(w_{2i} - w_{1i}/w_{1i}) \sim N(\mu_2, \sigma^2)$. Define X_i and Y_i as $X_i = \log(w_{2i} - w_{1i})$, $Y_i = \log(w_{2i} - w_{1i}/w_{1i})$. Then X_i and Y_i represent the logarithm of the absolute change and relative change of the measurements before and after the treatment. It can be shown that both X_i and Y_i are normally distributed. More details on the derivation of these results can be found in the Appendix.

Let μ_{AC} and μ_{RC} be the population means of the logarithm of the absolute change and relative change of a primary study endpoint of a given clinical trial, respectively. Thus, the hypotheses of interest based on the absolute change are given by

$$H_{01} : \mu_{AC} \leq \delta_0 \quad \text{vs.} \quad H_{a1} : \mu_{AC} > \delta_0,$$

where δ_0 is the difference of clinically importance. For the relative change, the hypotheses of interest are given by

$$H_{02} : \mu_{RC} \leq \Delta_0 \quad \text{vs.} \quad H_{a2} : \mu_{RC} > \Delta_0,$$

where Δ_0 is the difference of clinically importance. In practice, for a specific value of δ , where $\delta > \delta_0$, would be equivalent to what value of Δ with $\Delta > \Delta_0$ clinically.

In addition, if we consider that a patient is a responder if the logarithm of his/her absolute change of the primary study endpoint is greater than δ , then, it is of interest to test the following hypotheses:

$$H_{03} : P_{AC} = \eta \quad \text{vs.} \quad H_{a3} : P_{AC} > \eta,$$

where P_{AC} is the proportion of patients whose logarithm of the absolute change of the primary study endpoint is greater than δ . In practice, we may claim superiority (clinically) of the test treatment if we reject the null hypothesis at $\eta = 50\%$ and in favor of the alternative hypothesis that P_{AC} is greater than 50%. However, this lacks statistical

justification. For a non-inferiority (or superiority) trial, how can a non-inferiority margin of μ_{AC} be translated to the non-inferiority margin of P_{AC} ? Similarly, for the relative change, the hypotheses of interest are given by

$$H_{04} : P_{RC} = \eta \quad \text{vs.} \quad H_{a4} : P_{RC} > \eta,$$

where P_{RC} is the proportion of patients whose logarithm of the relative change of the primary study endpoint is greater than δ .

An Example

For example, consider a clinical trial for evaluation of possible weight reduction of a test treatment in female patients. Weight data from 10 subjects are given in Table 1. As it can be seen from Table 1, mean absolute change and mean percent change from pre-treatment are 5.3 lb. and 4.8%, respectively. If a subject is considered a responder if there is weight reduction by more than 5 lb. (absolute change) or by more than 5% (relative change), the response rates based on absolute change and relative change are given by 40% and 30%, respectively. For illustration purpose, Table 2 summarizes sample sizes required for achieving a desired power for detecting a clinically meaningful difference, say,

Table 1 Weight Data from Ten Female Subjects

Pre-treatment	Post-treatment	Absolute change	Relative change (%)
110	106	4	3.6
90	80	10	11.1
105	100	5	4.8
95	93	2	2.1
170	163	7	4.1
90	84	6	6.7
150	145	5	3.3
135	131	4	3.0
160	159	1	0.6
100	91	9	9.0
120.5 (30.5)	115.2 (31.5)	5.3	4.8

Table 2 Sample Size Calculation

Study endpoint	Clinical meaningful difference	Sample size required
Absolute Change	5 lb.	190
Relative Change	5 %	95
Responder 1 ^a	50% improvement	54
Responder 2 ^b	50% improvement	52

^aResponder is defined based on absolute change greater than or equal to 5.5 lb.

^bResponder is defined based on relative change greater than or equal to 5.5%.

by an absolute change of 5.5 lb. and a relative change of 5.5%, for the two study endpoints respectively.

As it can be seen from Table 2, a sample size of 190 is required for achieving an 80% power for detecting a difference of 5.5 lb. (post-treatment absolute change from pre-treatment) at the 5% level of significance, while a much larger sample size of 95 is required in order to have an 80% power for detecting a difference of 5.5% (relative change between post-treatment and pre-treatment) at the 5% level of significance. Based on responder's analysis, the results are different. Based on the analysis of responders, defined as subjects who have greater than or equal to 5.5 lb. of weight reduction, a total sample size of 54 subjects are needed for detecting a 50% improvement at the 5% level of significance. On the other hand, if we define a responder as a subject who has a greater than or equal to 5.5% relative weight reduction, then a total sample size of 52 subjects is required for achieving a 50% improvement at the 5% level of significance.

Remarks

As discussed above, sample sizes required for achieving a desired power for detecting a clinically meaningful difference at the 5% level of significance may be very different depending upon (i) the choice of study endpoint and (ii) clinically meaningful difference. In practice, it will be more complicated if the intended trial is to establish non-inferiority. In this case, sample size calculation will also depend on the selection of non-inferiority margin. To ensure the success of the intended clinical trial, the sponsor will usually carefully evaluate several clinical strategies for selecting the type of study endpoint, clinically meaningful difference, and non-inferiority margin during the stage of protocol development. Commonly considered study endpoints are

- measure based on absolute change;
- measure based on relative change;
- proportion of responders defined based on absolute change; and
- proportion of responders defined based on relative change.

In some cases, investigators may consider composite endpoint based on both absolute change and relative change. For example, in clinical trials for evaluation of the efficacy and safety of a compound for treating patients with active ulcerative colitis, a study endpoint utilizing the so-called Mayo score is often considered. The investigator may define a subject as a responder if he/she has a decrease from baseline in the total score of at least 3 points and at least 30% with an accompanying decrease in the subscore for rectal bleeding of at least one point or absolute subscore for rectal bleeding of 0 or 1 at Day 57. Note that the Mayo scoring system for assessment of ulcerative colitis activity

consists of three domains of (i) Mayo score, (ii) partial Mayo score, and (iii) mucosal healing.^[19]

For the four types of study endpoints derived from the clinical data collected from the sample patient population, clinically meaningful difference or non-inferiority margin that we would like to detect or establish could be based on either absolute change or relative change. For example, based on responder's analysis, we may want to detect a 30% difference in response rate or to detect a 50% relative improvement in response rate. As a result, there are a total of eight clinical strategies for assessment of the treatment effect. In practice, some strategies may lead to the success of the intended clinical trial (i.e., achieve the study objectives with the desired power), while other strategies may not. A common practice is for the sponsors to choose the strategy to their best interest. However, regulatory agencies may challenge the sponsor about the inconsistent results. This has raised the following questions: (i) how is the clinical information translated among different study endpoints (since they are obtained based on the same data collected from the same patient population)? and (ii), which study endpoint is telling the truth? These questions, however, remain unanswered. More research is required to address these questions. The current regulatory position is to require the sponsor to pre-specify which study endpoint will be used for assessment of the treatment effect in the study protocol without any scientific justification.

BRIDGING STUDIES

In recent years, the influence of ethnic factors on clinical outcomes for evaluation of efficacy and safety of study medications under investigation has attracted much attention from regulatory authorities, especially when the sponsor is interested in bringing an approved drug product from the original region (e.g., the United States or the European Union) to a new region (e.g., the Asian Pacific region). To determine whether clinical data generated from the original region are acceptable in the new region, the International Conference on Harmonization (ICH) issued a guideline on Ethnic Factors in the Acceptability of Foreign Clinical Data. The purpose of this guideline is not only to permit adequate evaluation of the influence of ethnic factors, but also to minimize duplication of clinical studies in the new region.^[20] This guideline is known as ICH E5 guideline.

As indicated in the ICH E5 guideline, a bridging study is defined as a study performed in the new region to provide pharmacokinetic (PK), pharmacodynamic (PD), or clinical data on efficacy, safety, dosage, and dose regimen in the new region that will allow extrapolation of the foreign clinical data to the population in the new region. The ICH E5 guideline suggests the regulatory authority of the new region to assess the ability to extrapolate foreign data based on the bridging data package, which

consists of (i) information including PK data and any preliminary PD and dose-response data from the complete clinical data package (CCDP) that is relevant to the population of the new region, and if needed, (ii) bridging study to extrapolate the foreign efficacy data and/or safety data to the new region. The ICH E5 guideline indicates that bridging studies may not be necessary if the study medicines are insensitive to ethnic factors. For medicines characterized as insensitive to ethnic factors, the type of bridging studies (if needed) will depend upon experience with the drug class and upon the likelihood that extrinsic ethnic factors could affect the medicine's safety, efficacy, and dose-response. On the other hand, for medicines that are ethnically sensitive, bridging study is usually needed since the populations in two regions are different. In the ICH E5 guideline, however, no criteria for assessment of the sensitivity to ethnic factors for determining whether a bridging study is needed are provided. Moreover, when a bridging study is conducted, the ICH guideline indicates that the study is readily interpreted as capable of bridging the foreign data if it shows that dose-response, safety, and efficacy in the new region are similar to those in the original region. However, the ICH does not clearly define the similarity.

Shih^[21] interpreted the ICH guideline as consistency among study centers by treating the new region as a new center of multicenter clinical trials. Under this definition, Shih^[21] proposed a method for assessment of consistency to determine whether the study is capable of bridging the foreign data to the new region. Alternatively, Shao and Chow^[22] proposed the concepts of reproducibility and generalizability probabilities for assessment of bridging studies. If the influence of the ethnic factors is negligible, then we may consider the reproducibility probability to determine whether the clinical results observed in the original region are reproducible in the new region. If there is a notable ethnic difference, the generalizability probability can be assessed to determine whether the clinical results in the original region can be generalized in a similar but slightly different patient population due to the difference in ethnic factors. In addition, Chow et al.^[17] proposed to assess bridging studies based on the concept of population (or individual) bioequivalence. Along this line, Hung^[23] and Hung et al.^[24] considered the assessment of similarity based on testing for non-inferiority between a bridging study conducted in the new region as compared to the previous conducted in the original region. This leads to the argument regarding the selection of non-inferiority margin.^[25] Note that other methods such as the use of Bayesian approach have also been proposed in literature.^[26]

Test for Consistency

For assessment of similarity between a bridging study conducted in a new region and studies conducted in the original region, Shih^[21] considered all of the studies conducted

in the original region as a multicenter trial and proposed to test consistency among study centers by treating the new region as a new center of a multicenter trial.

Suppose there are K reference studies in the CCDP. Let T_i denotes the standardized treatment group difference, i.e.,

$$T_i = \frac{\bar{x}_{Ti} - \bar{x}_{Ci}}{s_i \sqrt{(1/m_{Ti} + 1/m_{Ci})}},$$

where $\bar{x}_{Ti}(\bar{x}_{Ci})$ is the sample mean of $m_{Ti}(m_{Ci})$ observations in the treatment (control) group, and s_i is the pooled sample standard deviation. Shih^[21] considered the following predictive probability for testing consistency

$$p(T|T_i, i = 1, \dots, K) = \left(\frac{2\pi(K+1)}{K} \right)^{-K/2} \times \exp \left[-K(T - \bar{T})^2 / 2(K+1) \right].$$

Test for Reproducibility and Generalizability

On the other hand, when the ethnic difference is negligible, Shao and Chow^[22] suggest assessing reproducibility probability for similarity between clinical results from a bridging study and studies conducted in the CCPD. Let x be a clinical response of interest in the original region. Let y be similar to x but is a response in a clinical bridging study conducted in the new region. Suppose the hypotheses of interest are

$$H_0: \mu_1 = \mu_0 \quad \text{vs.} \quad H_a: \mu_1 \neq \mu_0.$$

We reject H_0 at the 5% level of significance if and only if $|T| > t_{n-2}$, where t_{n-2} is the $(1 - \alpha/2)$ th percentile of the t distribution with $n - 2$ degrees of freedom, $n = n_1 + n_2$,

$$T = \frac{\bar{y} - \bar{x}}{\sqrt{(n_1 - 1)s_1^2 + (n_0 - 1)s_0^2 / n - 2\sqrt{(1/n_1 + 1/n_2)}}},$$

and $\bar{x}, \bar{y}, s_0^2$, and s_1^2 are sample means and variances for the original region and the new region, respectively. Thus, the power of T is given by

$$p(\theta) = P(|T| > t_{n-2}) = 1 - \mathfrak{Z}_{n-2}(t_{n-2}|\theta) + \mathfrak{Z}_{n-2}(-t_{n-2}|\theta),$$

where

$$\theta = \frac{\mu_1 - \mu_0}{\sigma \sqrt{(1/n_1 + 1/n_0)}},$$

and $\mathfrak{Z}_{n-2}(\bullet|\theta)$ denotes the cumulative distribution function of the non-central t distribution with $n - 2$ degrees of freedom and the non-centrality parameter θ . Replacing θ in the power function with its estimate $T(x)$, the estimated power

$$\hat{p} = P(T(x)) = 1 - \mathfrak{Z}_{n-2}(t_{n-2}|T(x)) + \mathfrak{Z}_{n-2}(-t_{n-2}|T(x))$$

is defined as a reproducibility probability for a future clinical trial with the same patient population. When the ethnic difference is notable, Shao and Chow^[22] recommend assessing so-called generalizability probability for similarity between clinical results from a bridging study and studies conducted in the CCPD.

Test for Similarity

Using the criterion for assessment of population (individual) bioequivalence, Chow et al.^[17] proposed the following measure of similarity between x and y :

$$\theta = \frac{E(x-y)^2 - E(x-x')^2}{E(x-x')^2/2},$$

where x' is an independent replicate of x and y , x , and x' are assumed to be independent. Since a small value of θ indicates that the difference between x and y is small (relative to the difference between x and x'), similarity between the new region and the original region can be claimed if and only if $\theta < \theta_U$, where θ_U is a similarity limit. Thus, the problem of assessing similarity become a problem of testing the following hypotheses

$$H_0: \theta \geq \theta_U \quad \text{vs.} \quad H_a: \theta < \theta_U.$$

Let $k=0$ indicate the original region and $k=1$ indicates the new region. Suppose that there are m_k study centers and n_k responses in each center for a given variable of interest. For simplicity, we only consider the balanced case where centers in a given region have the same number of observations. Let z_{ijk} be the i th observation from the j th center of region k , b_{jk} be the between-center random effect, and e_{ijk} be the within center measurement error. Assume that

$$z_{ijk} = \mu_k + b_{jk} + e_{ijk}, \quad i = 1, \dots, n_k, \quad j = 1, \dots, m_k, \quad k = 0, 1,$$

where μ_k is the population mean in region k , $b_{jk} \sim N(0, \sigma_{bk}^2)$, $e_{ijk} \sim N(0, \sigma_{wk}^2)$, and $\{b_{jk}\}$ and $\{e_{ijk}\}$ are independent. Under the above model, the criterion for similarity becomes

$$\theta = \frac{(\mu_0 - \mu_1)^2 + \sigma_{r1}^2 - \sigma_{r0}^2}{\sigma_{T0}^2},$$

where $\sigma_{Tk}^2 = \sigma_{bk}^2 + \sigma_{wk}^2$ is the total variance (between center variance plus within center variance) in region k . The above hypotheses are equivalent to

$$H_0: \varsigma \geq 0 \quad \text{vs.} \quad H_a: \varsigma < 0,$$

where $\varsigma = (\mu_0 - \mu_1)^2 + \sigma_{T1}^2 - (1 + \theta_U)\sigma_{T0}^2$.

CONCLUDING REMARKS

Translational medicine is a multi-disciplinary entity that bridges basic scientific research with clinical development. As the expense in developing therapeutic pharmaceutical compounds continues to increase and the success rates for getting such compounds approved for marketing and to the patients needing these treatments continues to decrease, a focused effort has emerged to improve the communication and coordination of planning between basic and clinical science. This will likely lead to more therapeutic insights being derived from new scientific ideas, and more feedback being provided back to research so that approaches are better targeted. Translational medicine spans all the disciplines and activities that lead to making key scientific decisions as a compound traverses across the difficult preclinical-clinical divide. Many argue that improvement in decision-making about what doses and regimens should be pursued in the clinic—based on the likely human safety risks of a compound, the likely drug interactions, and the pharmacologic behavior of the compound—is the most critical step in the entire development process. Many of these decisions and the path for uncovering this information within later development are defined at this specific time within the drug development process. Improving these decisions will likely lead to a substantial increase in the number of safe and effective compounds available to combat human diseases.

Abstract

This entry discusses hypothesis testing and confidence intervals for determining trend estimation, and provides several models and methods for analysis and a sample analysis for further illustration and application of trend estimations.

OVERVIEW

In dose-effect data analysis, it is of interest to examine the effect (e.g., desirable effect or adverse effect) of different dosages of a drug or chemical in a system (e.g., an organ or a cell). Knowledge of the relationship between dosage and clinical response (effectiveness and adverse effects) is important for the safe and effective use of drugs in individual patients. For example, benzyl chloride, an occupational toxicant, is a colorless liquid with a pungent smell. It causes marked irritation of mucous membranes and conjunctiva. In various laboratory studies, the substance was shown to be carcinogenic after subcutaneous, epicutaneous, and intragastric administration to rats or mice; both local and systematic tumors were induced after intestinal uptake of benzyl chloride. In an animal carcinogenesis experiment,^[1] groups of 52 male mice were given benzyl chloride doses of 0, 50, or 100 mg/kg body weight in corn oil by gavage, three times weekly for two years. The proportions of mice with forestomach carcinomas and papillomas at the end of the study are reported in Table 1. In general, it is the purpose of dose-response trend analysis to examine if, for instance, the cure rate (risk) of certain disease (side effects) increases with increased intake (exposure) to a certain drug (toxicant). In this entry, the response of the subject will be assumed to be binary (e.g., absence or presence of a certain outcome), and the logistic model will be used to describe the dose-response relationship.

Assume that K doses of a substance are tested in an experiment, and that the k -th dose (denoted as x_k) is administered to n_k subjects, of whom r_k respond. In a case-control epidemiological study, r_k is the number of cases, and $n_k - r_k$ is the number of controls for the k th dose level. Let π_k be the probability that a subject shows response or the probability of there being a case at the k th dose level.

We assume independence among individuals within doses and among doses, and assume that the response

probability π_k satisfies a logit model. The model is defined as:

$$r_k \sim \text{Bin}(n_k, \pi_k), \quad \pi_k = \frac{1}{1 + \exp(\alpha + \beta x_k)}, \quad (1)$$

for $k = 1 \dots K$. Parameter β , which is called the trend parameter, measures the dose-response relationship or the association between the log-odds ratio (of being a case vs. being a control) and dose level. This is the parameter of interest. Parameter α is usually the nuisance parameter, i.e., parameter of no interest. The likelihood function of the observed counts $(r_1, \dots, r_k)$ is given by

$$L(\alpha, \beta) = \prod_{k=1}^K \binom{n_k}{r_k} \pi_k^{r_k} (1 - \pi_k)^{n_k - r_k} \quad (2)$$

$$\propto \frac{\exp\left[\alpha \sum_k r_k + \beta \sum_k x_k r_k\right]}{\prod_k \left[1 + \exp(\alpha + \beta x_k)\right]^{n_k}}. \quad (3)$$

Maximum likelihood estimates of α and β can be calculated by maximizing the above likelihood.

HYPOTHESIS TESTING AND CONFIDENCE INTERVAL

Asymptotic Approach

For the hypothesis testing method, it suffices to test the following hypotheses:

$$H_0: \beta = 0 \quad \text{vs} \quad H_A: \beta \neq 0. \quad (4)$$

In this case, a rejection of the null hypothesis indicates a dose-response trend. For the confidence interval method,

one can construct a $(1 - \gamma) \times 100\%$ confidence interval for β . If the value 0 is lying outside the constructed confidence interval, one may conclude the existence of a dose-response trend. In particular, if the lower (upper) confidence limit is greater (less) than zero, a positive (negative) linear trend is anticipated. In practice, one can perform either of the methods via (unconditional) asymptotic and (conditional) exact approaches.

For the asymptotic approach, the unconditional likelihood inference is based on maximizing the likelihood function in Eq. (3). Usually, asymptotic statistics (e.g., likelihood ratio, score, and Wald) can be used to test the null hypothesis in Eq. (4). Take the Wald statistic as an example. Let $\hat{\beta}$ be the maximum likelihood estimate of β in Eq. (3) and $s\beta$ the corresponding standard error. The Wald statistic calculates a Z statistic, which is $z = \hat{\beta} / s\beta$. According to the hypothesis testing method, a dose-response trend is guaranteed at γ level if $|z| \geq z_{\gamma/2}$, where $z_{\gamma/2}$ is the $(1 - \gamma/2) \times 100\%$ percentile of the standard normal distribution. Equivalently, one may construct a $(1 - \gamma) \times 100\%$ Wald confidence interval for β , i.e., $\hat{\beta} \pm z_{\gamma/2} s\beta$. According to the confidence interval method, a dose-response trend exists if 0 is not in $(\hat{\beta} - z_{\gamma/2} s\beta, \hat{\beta} + z_{\gamma/2} s\beta)$. For the carcinogenicity study with benzyl chloride in Table 1, we have $z = 5.50$ with p -value < 0.0001 , and we have reason to believe that there exists a dose-response trend between the carcinoma rate and the dosage of benzyl chloride. In addition, the 95% confidence interval for β is given by (1.98, 4.16), whose lower confidence limit is greater than 0. That further indicates a positive trend between the carcinoma rate and the dosage of benzyl chloride. It is noteworthy that the asymptotic approach is reliable only when the sample size is large enough.

Conditional Exact Approach

When the total sample size (i.e., $n = \sum_k n_k$) is small or the data structure (i.e., $r = (r_1, \dots, r_k)$) is sparse, the asymptotic approach is generally believed to be unreliable. Under these situations, exact inference, based on enumerating the exact distribution of sufficient statistics of the parameter of interest, is widely recommended.^[2-4] To perform conditional inference, we first note that the sufficient statistics for the parameters α and β can be shown to be $s = \sum_k r_k$ and $t = \sum_k x_k r_k$, respectively. To eliminate the nuisance parameter α from the analysis,^[5,6] one can consider the distribution of $r = (r_1, \dots, r_k)'$ conditioned on s . That is,

$$\Pr[r | s] = \frac{\prod_k \left[\binom{n_k}{r_k} \exp(\beta x_k r_k) \right]}{\sum_{u \in \Omega(s)} \prod_k \left[\binom{n_k}{u_k} \exp(\beta x_k u_k) \right]},$$

where $\Omega(s) = \{u = (u_1, \dots, u_K) : 0 \leq u_k \leq n_k, k = 1, \dots, K \text{ s.t. } \sum_k u_k = s\}$. Particularly, the conditional distribution of t given s is given by

$$\Pr[t | s; \beta] = \frac{c(s, t) \exp(\beta t)}{\sum_{v \in \Gamma} c(s, v) \exp(\beta v)} \text{ with}$$

$$c(s, t) = \sum_{u \in \Omega(t|s)} \prod_k \binom{n_k}{u_k},$$

where $\Omega(t | s) = \{u : u \in \Omega(s) \text{ and } \sum_k x_k u_k = t\}$ and $\Gamma_s = \{v : v = \sum_k x_k u_k \text{ and } u \in \Omega(s)\}$.

To illustrate the implementation of the hypothesis testing method based on the conditional exact approach, we consider the following famous chi-square Cochran-Armitage statistic for linear trend^[7,8] $X^2(s, t) = t^2 / V_t$, where $V_t = [s(n - s) / (n(n - 1))] \sum_k n_k (x_k - \bar{x})^2$ and $\bar{x} = \sum_k x_k / K$. To determine the p -value of $X^2(s, t)$ under H_0 , we note that the conditional distribution of t given s is

$$f_0(t | s) = \frac{c(s, t)}{\sum_{v \in \Gamma} c(s, v)}.$$

Hence, an exact conditional p -value based on $X^2(s, t)$ can be computed as

$$p_e = \sum_{X^2(s, t) \leq X^2(s, v)} f_0(v | s).$$

We may then conclude the existence of a dose-response trend at γ level if p_e is less than or equal to γ . It is noteworthy that a lot of existing statistics (e.g., Helmert, reverse-Helmert, maximin, pairwise, linear, analogon, and reverse-analogon statistics) have been derived for detecting dose-response trend for dichotomous endpoints,^[9] and the above conditional exact p -value calculation method can be readily extended to these statistics. For the confidence interval method based on the exact approach, the exact $(1 - \gamma) \times 100\%$ confidence interval for β is given by (β_L, β_U) , where β_L and β_U satisfy the following equations

$$G(\beta_L; t) = 1 - \Pr[T < t | s; \beta_L] = \gamma / 2 \text{ and}$$

$$H(\beta_U; t) = \Pr[T \leq t | s; \beta_U] = \gamma / 2.$$

Again, a dose-response trend exists if 0 is not in (β_L, β_U) . For the carcinogenicity study with benzyl chloride in Table 1, we have $p_e < 0.0001$, and there exists a dose-response trend between the carcinoma rate and dosage of benzyl chloride.

Table 1 Proportions of Mice That Developed Forestomach Carcinomas and Papillomas in the Carcinogenicity Study with Benzyl Chloride

Forestomach carcinomas and papillomas	Dosage (mg/kg body weight)		
	0	50	100
Yes	0	4	32
No	51	48	20

Moreover, the 95% exact confidence interval for β is given by (1.96, 4.46), whose lower confidence limit is greater than 0, and a positive trend between the carcinoma rate and dosage of benzyl chloride can be concluded.

The methods and approaches discussed in this section have been available from the LOGISTIC procedure in Release 8.1, SAS/STAT software. Readers should notice that the linear logistic regression model has been assumed throughout this section. Unfortunately, methods (especially the Cochran-Armitage statistic) discussed in this section are sometimes wrongly applied and erroneously interpreted as a linear trend analysis without scrutiny of the fit of the underlying linear logistic model.^[10] Hence, readers are strongly recommended to test the linearity assumption before a linear trend is claimed.

In theory, exact unconditional inference can be similarly developed for logistic regression analysis.^[11] Since the exact unconditional method involves tedious computations (e.g., maximizing the nuisance parameters over their support and exhausting all possible data configurations), it seems to be applicable to simple situations such as 2×2 contingency table analyses.

ESTIMATION

Trend Estimation by Using an Empirical Log-Odds Ratio

In practice, we can use an empirical log-odds ratio to estimate the trend parameter β . Without loss of generality, let the first dose class be the baseline group with zero dosage and let y_k be the empirical log-odds ratio or adjusted log-odds ratio at the k th dose level, compared with the baseline group for $k = 2, \dots, K$. If we define $y = (y_2, \dots, y_K)'$, then an approximation approach for trend estimation is to fit a linear regression through the origin, i.e.,

$$y_k = \beta x_k + s_k \varepsilon_k, \quad \text{for } k = 2, \dots, K, \quad (5)$$

where ε_k 's are assumed to be standard normal errors, and s_k is the standard error of y_k . For crude log-odds ratio, s_k can be approximated by $1/r_1 + 1/(n_1 - r_1) + 1/r_k + 1/(n_k - r_k)$.^[12] In this model, we do not consider group correlation for log-odds ratios. Applying least squares to Eq. 5, we obtain the estimate of the dose-response regression slope $\hat{\beta}$ and its

$$\text{variance as } \hat{\beta} = \frac{\sum_{i=1}^m \hat{\beta}_i / s_{\beta i}^2}{\sum_{i=1}^m 1 / s_{\beta i}^2}, \text{ and } \text{var}(\hat{\beta}) = \frac{1}{\sum_{i=1}^m 1 / s_{\beta i}^2}.$$

Since the log-odds ratios are calculated with the same baseline group, they are correlated. To allow for within-study correlation between log-odds ratios, we use the following model^[13]

$$y_k = \beta x_k + \varepsilon_k, \text{ with} \quad (6)$$

$$\varepsilon = (\varepsilon_2, \dots, \varepsilon_K) \sim N(0, \Sigma),$$

where the $(j-1, k-1)$ -th off-diagonal element of Σ is given by $r_{jk} s_j s_k$ with $r_{jk} \approx v_j v_k / (v_j v_k)^{1/2}$, $v_1 = 1/r_1 + 1/(n_1 - r_1)$, and $v_k = 1/r_k + 1/(n_k - r_k)$ for $j, k = 2, \dots, K$. Here, v_k is the approximated standard error of the crude log-odds ratio. The estimate of β and its standard error are then

$$\text{given by } \hat{\beta} = \frac{\sum_{k=2}^K x_k y_k / s_k^2}{\sum_{k=2}^K x_k^2 / s_k^2}; \quad s_{\beta}^2 = \frac{1}{\sum_{k=2}^K x_k^2 / s_k^2} \text{ where } x = (x_2, \dots, x_K)'$$

Trend Estimation with Grouped Data

In trend estimation, the dose (exposure) levels for each subject are often not recorded exactly, but are grouped into class intervals. We suppose that exposure (dose) is an underlying continuous covariate belonging to observable intervals J_k , so that x_k in J_k . For the example of breast cancer and alcohol use, alcohol consumption can only be recorded as grouped data, because of the nature of the questionnaire, which are shown as the first column in Table 2. The customary method of analysis is to assign a single value x_k as a representative of J_k . In Table 2, the assigned values for x_k are listed in the second column. If the class intervals cover a wide range of levels of exposure, the assigned-value method is clearly unsatisfactory. Different choices of assigned values will give different estimates. Thus, assigning a single value to each J_k leads to inaccurate estimates and the underestimation of variance.^[14]

Suppose the exposure levels of all individuals in a particular study are sampled from some distribution with a probability density function $f(x)$. Then, if the probability of being a case given dose x is π_x , the probability that an individual in class interval J is a case is

$$\pi_J = \frac{\int_J \pi_x f(x) dx}{\int_J f(x) dx}. \quad (7)$$

Table 2 Case-control data on alcohol use and breast cancer

Alcohol (g/day)	Assigned dose x	No. of cases	No. of controls	Crude OR	Adjusted OR (CI)
0	0	165	172	1.00	1.00
<2.5	2	74	93	0.83	0.80 (0.51–1.27)
2.5–9.3	6	90	96	0.98	1.16 (0.73–1.85)
>9.3	11	122	90	1.41	1.57 (0.99–2.51)

The observed number of individuals in this class interval who are cases therefore follows a binomial distribution with Eq. (7) as the probability of success. If we continue to adopt the logit model with $\pi_x = 1 / (1 + \exp(\alpha + \beta x))$, the likelihood for (α, β) is still given by Eq. 2 with π_k being replaced by π_{j_k} in Eq. 7. Following the derivation given in Shi and Copas,¹⁴ β can be estimated by maximizing the following log-likelihood function:

$$\hat{\beta} = s_{\beta}^2 x' \Sigma^{-1} y, \quad s_{\beta}^2 = [x' \Sigma^{-1} x]^{-1}$$

where $A(\beta) = (A_2(\beta), \dots, A_k(\beta))$, $A_k(\beta) = \log[p_k(\beta) / (1 - p_k(\beta))]$, and $-\frac{1}{2} \log |\Sigma| - \frac{1}{2} \{y - A(\beta)\}' \Sigma^{-1} \{y - A(\beta)\}$, with $q_k = \int_{j_k} f(x) dx$ and $\hat{\alpha} = \log[r_1 / (n_1 - r_1)]$. This approach is also approximately valid for an adjusted log-odds ratio, provided the covariate adjustments are not too large.

To implement this procedure, we need to know the dose distribution $f(x)$. We may use a parametric model fitted to the observed frequencies of the dose intervals. For the example of breast cancer and alcohol use, a log-normal distribution is used. In principle, any parametric or non-parametric method could be used to estimate the density function $f(x)$. Prior knowledge from historical data can also be incorporated.

COMBINING DOSE-RESPONSE DATA

In epidemiology and other areas, different studies on a similar topic may fail to give meaningful or statistically significant conclusions addressing a particular issue. Meta-analysis is used to summarize and combine results from these individual studies and provide an overall conclusion.^[15]

Meta-Analysis for Trend Estimation

Suppose there are m studies in a meta-analysis, with the log-odds ratios (or their adjusted values) from individual studies satisfying model Eq. (6). Let $\hat{\beta}_i$ and s_{β_i} be the estimate of β_i and its standard error calculated from Eq. (6) for $i = 1, \dots, m$. A fixed-effect meta-analysis model assumes that the true value of β is constant across the studies, i.e.,

$$\hat{\beta}_i \sim N(\beta, s_{\beta_i}^2). \quad (8)$$

This gives the pooled estimate of the trend parameter and its variance as

$$\sum_{i=1}^m \left\{ -\frac{1}{2} \log(\tau^2 + s_{\beta_i}^2) - \frac{1}{2} (\hat{\beta}_i - \beta)^2 / (\tau^2 + s_{\beta_i}^2) \right\}.$$

Since the design quality and sample selection could vary extremely among different studies,^[16] this may lead to the

problem of heterogeneity in combining dose-response data. To allow for heterogeneity among different studies, we assume that

$$\hat{\beta}_i \sim N(\beta, s_{\beta_i}^2 + \tau^2). \quad (9)$$

Here, the coefficient β measures the overall association between log-odds ratio and dose level, and τ measures the magnitude of the variation between studies. The maximum likelihood estimate of (β, τ) is calculated by maximizing

$$p_k(\beta) = \frac{1}{q_k} \int \frac{\exp(\hat{\alpha} + \beta x)}{1 + \exp(\hat{\alpha} + \beta x)} f(x) dx$$

The standard error of β is calculated by $1 / \sum (\tau^2 + s_{\beta_i}^2)^{-1}$, where τ is evaluated at its maximum likelihood estimate. We can use a hypothesis testing method to test $H_0: \beta = 0$. The p -value can be calculated by using, for example, the likelihood ratio test. The confidence interval method can also be used here. This is an easy approach, which can be readily extended to grouped values of x_k discussed in the previous section. A comprehensive discussion for meta-analysis and trend estimation is given in Shi and Copas.^[14]

The method discussed in this section is based on the normal approximation of $\hat{\beta}_i$ in Eq. 8 or Eq. (9). However, if the total sample size in some studies is small, the normal approximation may be not valid. Shi^[17] developed an exact approach based on binomial distributions. The method also allows for the heterogeneity among different studies and addresses the problem of publication bias.

EXAMPLE: ASSOCIATION BETWEEN BREAST CANCER AND ALCOHOL USE

Inference in a Single Study

Table 2,^[18] reports data from a case-control study investigating the association between the consumption of alcohol and the risk of breast cancer. Here, for each of the 451 cases and 415 controls, we have an estimate of alcohol consumption grouped into one of four exposure bands, including the baseline group with zero dose. Each row gives an estimate of the odds of being a case versus being a control, and the estimates of the odds ratios reported in the fifth column. In practice, as in this study, we usually adjust these estimates according to other covariates known to be related to risk, such as age. The sixth column in Table 2 gives the adjusted odds ratios and their confidence limits.

We first take the x_k 's to be the assigned dose levels listed in the second column of Table 2, and use model Eq. (6) to allow for within-group correlation for log-odds ratios. Using the formulas given after model Eq. 6 yields the maximum likelihood estimate $\hat{\beta} = 0.0479$ with standard error 0.205.

However, due to the nature of the questionnaire, we can only record a class interval for a dose level, which is reported in the first column of Table 2. By using all the observed frequencies of the dose intervals for similar studies (they are the data collected and used in meta-analysis as discussed below), the estimated density function $f(x)$ for dose level has a log-normal distribution. By using the method for grouped dose level, we have the estimates $\hat{\beta} = 0.019$ and the standard error 0.0094.

Meta-Analysis and Trend Estimation

Longnecker et al.^[19] and Greenland and Longnecker^[20] conducted a system review for studying the overall association between alcohol consumption and risk of breast cancer. We consider 13 studies here to compare different methods for meta-analysis. We first use the same assigned values for x_k as used by those authors of these individual studies. Those assigned values are given based on the authors' experiences or some historical data, and therefore may not be very accurate. This method gives the overall estimate of the trend parameter as 0.0088, with standard error 0.0014, based on the fixed-effect model Eq. 8. On the other hand, the random-effect model Eq. 9 produces the random-effect trend estimate of 0.0112, with standard error 0.0026 and $\hat{\tau} = 0.0065$. The corresponding p -value for $H_0: \beta = 0$ is less than 0.001, suggesting that the association between breast cancer and the consumption of alcohol is highly significant.

Suppose that alcohol consumption has a log-normal distribution over all the subjects in these studies. Taking a log-transformation for alcohol consumption and fitting all the observed frequencies of the dose intervals to a normal distribution gives the estimated normal distribution, with mean 1.533 and standard error 1.380. We next take $f(x)$ to be this fitted log-normal distribution and maximize the log-likelihood after model Eq. 7. This gives the estimate of β_i in each of the individual studies. The results are reported in the columns named "Grouped values approach" in Table 3.

For comparison purpose, we set the x_k 's by their expected log dose calculated from the fitted dose distribution (i.e., the log-normal distribution). This provides the column named "Mean approach" in Table 3. Comparing the results reported in the first paragraph of this section with the results of "Mean approach" reported in Table 3, we confirm that the estimates are very sensitive to the choices of the assigned values of dose levels.

When the studies are pooled together using the fixed effects model, the assigned values approaches suggest a much stronger dose trend than the grouped values approach. Based on the random effects model, the estimates from the assigned values approaches are even higher. The value of $\hat{\tau}$ for the grouped values approach is much smaller than that for the assigned values approaches. In fact, the fixed and random effects models are almost indistinguishable when

Table 3 Meta Analysis Estimates for Alcohol and Breast Cancer Studies

Study number	Mean approach		Grouped values approach	
	β	SE	β	SE
1	0.0054	0.0028	0.0027	0.0016
2	0.0111	0.0044	0.0070	0.0029
3	0.0149	0.0030	0.0067	0.0010
4	0.0328	0.0164	0.0157	0.0069

	0.0084	0.0012	0.0055	0.0007
Pooled estimate by random effect model				
	0.0090	0.0016	0.0054	0.0009
$\hat{\tau}$	0.0034		0.0013	
p -value of $\tau = 0$	0.1164		0.3814	

the grouped values approach is used. It seems that the extra uncertainty through the variability of dose levels within classes has almost entirely explained the heterogeneity. The consequence of having a large value of τ is because more weight is assigned to those smaller studies.

Based on the assigned-value approach, the random effects trend estimate is 0.0112, implying that one extra drink daily (about 13g of alcohol, according to Longnecker^[21]) increases the risk by about 16%. By the grouped values approach, the risk increases only about 7% (from an estimated trend of 0.0054), which is less than half of the percentage reported by the assigned-value approach. The latter seems to be a more reasonable estimate according to a latest extensive meta-analysis.²¹

CONCLUSION

When the total sample size is not too small, we can usually use the asymptotic approach to calculate p -value for hypothesis testing and confidence interval construction for trend parameter β . In practice, we can simply use an empirical log-odds ratio to estimate the value of β . This method can be easily extended to meta-analysis, which combines many small dose-response data to give an overall result.

However, when the total sample size is small, or the data structure is sparse, the exact conditional approach is usually recommended. The exact approaches for hypothesis testing and confidence interval method are discussed in this entry. For meta-analysis based on exact approach, refer to Shi.^[17]

Due to the nature of the experiments in epidemiological studies and other areas, grouped-dose data are quite common. As shown in this entry, the estimate of trend parameters can be very sensitive to the choice of the assigned values of dose levels. We therefore recommend an approach that considers the grouped-dose data discussed in this entry.

The computation involved in the models discussed in this entry is quite straightforward and can be implemented in SAS or R. Program codes for meta-analysis and trend estimation are available at <http://www.staff.ncl.ac.uk/j.q.shi>.

Two-Stage Adaptive Design: Analysis

Shein-Chung Chow, PhD

Duke University School of Medicine, Durham, North Carolina, U.S.A.

Min Lin, PhD

Food and Drug Administration, Silver Spring, Maryland, U.S.A.

Abstract

The purpose of an adaptive design is not only to efficiently identify clinical benefits of the test treatment under investigation, but also to increase the probability of success in the drug development process. One of the commonly considered adaptive designs is a two-stage seamless adaptive design, which addresses study objectives within a single trial that are normally achieved through separate trials. In practice, the two-stage seamless adaptive designs can be classified into four categories depending on study objectives and study endpoints at different stages. In this article, a comparison between the two-stage seamless adaptive designs and the traditional approach is briefly outlined. An overview of the characteristics and analysis methods for four categories of two-stage seamless adaptive designs is provided. Issues and approaches regarding the sample size calculation for a two-stage seamless adaptive design are also discussed.

Keywords: Adaptive designs; Sample size calculation; Seamless phase II/III; Two-stage.

INTRODUCTION

Adaptive design clinical trials have gained much attention over decades. The purpose of an adaptive design is not only to efficiently identify clinical benefits of the test treatment under investigation, but also to increase the probability of success in the drug development process. With an adaptive design, the investigators have a prospectively planned opportunity for modification of one or more specified aspects of the study design and hypotheses based on accumulating data from subjects in the ongoing study.^[1,2] The use of adaptive design methods in clinical trials may allow the researchers to react earlier to surprises at the interim looks and to correct assumptions used at the planning stage. Regardless of positive or negative interim results of an adaptive design study, its flexible features can be ethical with respect to both efficacy and safety of the treatment under investigation and may better reflect real-world medical practice. However, adaptations applied after the review of interim (unblinded) data may raise some critical concerns to the accurate and reliable evaluation of the test treatment. One major concern is how to control the overall type I error rate at a prespecified level of significance. It is also of concern that the scientific integrity and validity of a trial may not be warranted due to operational biases.

One of the commonly considered adaptive designs is a two-stage seamless adaptive design, which addresses study objectives within a single trial that are normally achieved through separate trials. In practice, a typical two-stage seamless adaptive design consists of two stages (phases),

namely, a learning (or exploratory) phase (Stage 1) and a confirmatory phase (Stage 2).^[3,4] The learning phase provides the investigator the opportunities to obtain information regarding the uncertainty of the test treatment under investigation and to stop the trial early due to safety and/or futility/efficacy based on accrued data. The objective of the confirmatory phase is to confirm the findings observed from the learning phase. At the end of the study, one would use data collected from both stages in the final analysis. The idea behind a two-stage seamless adaptive design trial is to reduce lead time between two traditional studies.

In practice, the commonly employed two-stage seamless adaptive designs include a two-stage seamless phase I/II adaptive design and a two-stage seamless phase II/III adaptive design. For a two-stage seamless phase I/II adaptive design, the objective of the first stage may be biomarker development, whereas the study objective of the second stage is to establish early efficacy. For a two-stage seamless phase II/III adaptive design, the study objective is for treatment selection (or dose finding) in the first stage, and the study objective of the second stage is efficacy confirmation.

In what follows, a comparison between the two-stage seamless adaptive designs and the traditional approach is briefly outlined. An overview of the characteristics and statistical methods for different types of two-stage seamless adaptive designs is provided. Issues and approaches regarding the sample size calculation for a two-stage seamless adaptive design are discussed. Some concluding remarks are then given.

TWO-STAGE SEAMLESS ADAPTIVE DESIGN VS. TRADITIONAL APPROACH

Possible advantages and disadvantages of a two-stage seamless adaptive design have been noted.^[3–5] As mentioned earlier, a two-stage seamless adaptive design may help in reducing lead time between two studies in the traditional approach. For example, it usually takes 6–12 months to kick off the phase III study after the completion of the phase II trial. The lead time between phase II and phase III trials are generally used (i) to clean and lock database, perform statistical analysis, and write a final clinical study report of the phase II trial; and (ii) to finalize the study protocol, initiate participating study site/centers, and obtain institutional review board (IRB) review/approval of the phase III study. As a comparison, the study protocol of a two-stage seamless phase II/III adaptive design covers both phase II (Stage 1) and phase III (Stage 2) studies. Thus, there is no need to resubmit the protocol for IRB approval during the lead time between Stage 1 and Stage 2. In addition, compared to the traditional approach, fewer subjects may be required for a two-stage seamless phase II/III adaptive design because it allows investigators to fully utilize data collected from both stages for a combined analysis. However, the use of a two-stage seamless phase II/III adaptive design may not save the overall time of a product development as it may require extra upfront planning time to provide design justification, possibly perform extensive simulation studies, and go through multiple regulatory review cycles. The start of a two-stage seamless adaptive design study can be significantly delayed due to those processes.

ANALYSIS OF TWO-STAGE SEAMLESS ADAPTIVE DESIGN

Types of Two-Stage Seamless Adaptive Design

Depending upon study objectives and study endpoints at different stages, two-stage seamless adaptive designs can be classified into the four categories^[3,4]: Category I designs—the study objectives and the study endpoints are the same; Category II designs—the study objectives are the same but the study endpoints are different; Category III designs—the study objectives are different but the study endpoints are the same; Category IV designs—the study objectives and the study endpoints are different. Note that different study objectives could be treatment selection or dose finding for Stage 1 and efficacy confirmation for Stage 2, whereas different study endpoints are usually referred to biomarker (surrogate) endpoints, or clinical endpoints with a shorter duration for Stage 1 versus clinical endpoints for Stage 2. Category I design is often viewed as a similar design to a traditional group sequential design with one interim analysis. In this article,

our emphasis is on Category II designs. The results would be similarly obtained to address the issues in Category III and Category IV designs.

Analysis of Category I Designs

As mentioned previously, Category I design with the same study objectives and study endpoints at both stages is similar to a typical group sequential design with one planned interim analysis. However, standard statistical methods for group sequential design may not be appropriate due to various adaptations applied in Category I designs. Available analysis approaches include (i) Fisher's methods for combining independent p -values,^[6–8] (ii) weighted test statistics,^[9] (iii) the conditional error function method,^[10,11] (iv) conditional power approaches,^[12] and (v) Chang's method based on the approach of sum of p -values (MSP).^[13] In this section, for illustration purposes, we apply the general framework of the MSP to the K -stage seamless adaptive designs as outlined in the works of Chang^[13] and Chow and Chang.^[14] The results can be simplified to fit a two-stage seamless adaptive design.

Let us consider a K -stage seamless adaptive design with a hypothesis test at each of K stages. One may want to treat it as a clinical trial with K preplanned interim analyses, whereas the final analysis is the K th interim analysis. The objective of the trial can be written as the intersection of the individual hypothesis tests from the interim analyses:

$$H_0 : H_{01} \cap \dots \cap H_{0K}, \quad (1)$$

where $H_{0i}, i = 1, \dots, K$, is the null hypothesis to be tested based on a subsample at the i th stage. Without loss of generality, the hypothesis test can be given as

$$H_{0i} : \eta_{i1} \geq \eta_{i2} \quad \text{vs.} \quad H_{ai} : \eta_{i1} < \eta_{i2}, \quad (2)$$

for comparing two treatment groups at the i th stage, where η_{i1} and η_{i2} are the responses of the two treatment arms, and we assume bigger values are better. One constraint is that rejection of any $H_{0i} : i = 1, \dots, K$ will result in the same clinical implication (e.g., new treatment is efficacious). Thus, all $H_{0i} : i = 1, \dots, K$ are constructed for testing the same endpoint within a trial. Note that the p -value p_i for the subsample at the i th stage is often uniformly distributed on $[0, 1]$ under H_0 when $\eta_{i1} = \eta_{i2}$. Following the idea of Fisher's combination approach,^[6–8] Chang^[13] considered a linear combination of the p -values to construct a test statistic for multiple-stage adaptive designs up to the k th stage:

$$T_k = \sum_{i=1}^k w_{ki} p_i, \quad i = 1, \dots, k, \quad (3)$$

where $w_{ki} > 0$. T_k is viewed as cumulative evidence against H_0 . As a result, the smaller the T_k is, the stronger the

evidence is. One can also consider $T_k = \sum_{i=1}^k p_i / K$, which can be treated as an average of the evidence against H_0 . Intuitively, stopping rules may be set up as

$$\begin{cases} \text{Stop for efficacy} & \text{if } T_k \leq \alpha_k \\ \text{Stop for futility} & \text{if } T_k \geq \beta_k, \\ \text{Continue} & \text{otherwise} \end{cases} \quad (4)$$

where T_k , α_k , and β_k are monotonic increasing functions of k , $\alpha_k < \beta_k$, $k = 1, \dots, K-1$, and $\alpha_K = \beta_K$. Note that α_k and β_k are referred to as the efficacy and futility boundaries, respectively. For a K -stage seamless adaptive design, it has to pass 1 to $(k-1)$ th stages to get to the k th stage. Thus, Chang^[13] defined a so-called proceeding probability as unconditional probability:

$$\begin{aligned} \psi_k(t) &= P(T_k < t, \alpha_1 < T_1 < \beta_1, \dots, \alpha_{k-1} < T_{k-1} < \beta_{k-1}) \\ &= \int_{\alpha_1}^{\beta_1} \dots \int_{\alpha_{k-1}}^{\beta_{k-1}} \int_{-\infty}^t f_{T_1 \dots T_k}(t_1, \dots, t_k) dt_k dt_{k-1} \dots dt_1, \end{aligned} \quad (5)$$

where $t \geq 0$, t_i , $i = 1, \dots, k$, is the test statistic at the i th stage, and $f_{T_1 \dots T_k}$ is the joint probability density function. Note that $\psi_k(t)$ is an unconditional probability. Therefore, one can calculate the error rate at the k th stage using

$$\pi_k = \psi_k(\alpha_k). \quad (6)$$

Therefore, the experiment-wise type I error rate is the sum of π_k , $k = 1, \dots, K$, because the type I error rates at different stages are mutually exclusive. That is,

$$\alpha = \sum_{k=1}^K \pi_k. \quad (7)$$

Hence, stopping boundaries can be determined with appropriate choices of α_k . The adjusted p -value can be calculated using the same approach in a classic group sequential design.^[15] Note that the p -value is equal to alpha spent $\sum_{i=1}^k \pi_i$ when the test statistic at the k th stage $T_k = t = \alpha_k$ (i.e., just on the efficacy stopping boundary). This is true regardless of which error spending function is used and consistent with the p -value definition of the traditional design. Chang^[13] defined the adjusted p -value corresponding to an observed test statistic $T_k = t$ at the k th stage as

$$p(t; k) = \sum_{i=1}^{k-1} \pi_i + \psi_k(t), \quad k = 1, \dots, K. \quad (8)$$

As compared to p_i in Eq. (3), the stage-wise (unadjusted) p -values from a subsample at the i th stage, $p(t; k)$, are adjusted p -values calculated from the test statistic, which are based on the cumulative sample up to the k th stage

where the trial stops. Note that Eqs. (7) and (8) are valid regardless of how p_i are calculated.

Analysis of Category II Designs

In this section, we consider a Category II two-stage seamless phase II/III adaptive design that has the same study objectives but different study endpoints. Without loss of generality, we further consider that the study endpoint for the Stage 1 (phase II) is a biomarker (or a surrogate endpoint) with continuous measurements, whereas the study endpoint for the Stage 2 (phase III) is a continuous clinical endpoint. Chow et al.^[16] proposed to obtain the predicted values of the clinical endpoint using data collected from the biomarker based on an established relationship between the biomarker and the clinical endpoint. In the final analysis, these predicted values are combined with the data collected at the confirmatory phase (Stage 2) to derive a statistical inference on the treatment effect of the test product under investigation.

Let x_i be the observed value of a biomarker (or a surrogate endpoint) from the i th subject in phase II (Stage 1), $i = 1, \dots, n$, and y_j be the observed value of the primary clinical endpoint from the j th subject in phase III (Stage 2), $j = 1, \dots, m$. We assume that x_i 's and y_j 's are independently and identically distributed with $E(x_i) = \nu$ and $\text{Var}(x_i) = \tau^2$, and $E(y_j) = \mu$ and $\text{Var}(y_j) = \sigma^2$, respectively. For simplicity, assume that x and y can be correlated with the following straight-line relationship

$$y = \beta_0 + \beta_1 x + \varepsilon, \quad (9)$$

where ε is the random error with zero mean and variance ε^2 . ε is assumed to be independent of x . In practice, if we consider that this relationship is well established, then the parameters β_0 and β_1 are assumed to be known. Hence, the observations x_i obtained in Stage 1 can be transformed into $\beta_0 + \beta_1 x_i$ (denoted by $\hat{y}_i$) using Eq. (9). $\hat{y}_i$ are then combined with those observations y_i collected in the Stage 2 to estimate the treatment mean μ . The following weighted mean estimator was proposed by Chow, Lu, and Tse^[16] as

$$\hat{\mu} = \omega \bar{\hat{y}} + (1 - \omega) \bar{y}, \quad (10)$$

where $\bar{\hat{y}} = \frac{1}{n} \sum_{i=1}^n \hat{y}_i$, $\bar{y} = \frac{1}{m} \sum_{j=1}^m y_j$, and $0 \leq \omega \leq 1$. In practice, ω is usually estimated by

$$\hat{\omega} = \frac{n/s_1^2}{n/s_1^2 + m/s_2^2}, \quad (11)$$

where s_1^2 and s_2^2 are the sample variances of $\hat{y}_i$'s and y_j 's, respectively. The corresponding estimator of μ is then denoted by

$$\hat{\mu}_{GD} = \hat{\omega} \bar{\hat{y}} + (1 - \hat{\omega}) \bar{y}, \quad (12)$$

which is referred to as the Graybill-Deal (GD) estimator of μ .^[17]

Based on the GD estimator, the comparison of the equality of the two treatment groups can be made by testing the following hypotheses:

$$H_0: \mu_A = \mu_B \quad \text{vs.} \quad H_1: \mu_A \neq \mu_B. \quad (13)$$

Let $\hat{y}_{it}$ be the predicted value (based on $\beta_0 + \beta_1 x_{it}$) of the clinical endpoint for the i th subject in phase II (Stage 1) and y_{ij} be the observed value of the clinical endpoint from the j th subject in phase III (Stage 2) under treatment, where $t=A$ or B . From Eq. (12), the GD estimator of μ_t is given by

$$\hat{\mu}_{GDt} = \hat{\omega}_t \bar{\hat{y}}_t + (1 - \hat{\omega}_t) \bar{y}_t, \quad (14)$$

where $\bar{\hat{y}}_t = \frac{1}{n_t} \sum_{i=1}^{n_t} \hat{y}_{it}$, $\bar{y}_t = \frac{1}{m_t} \sum_{j=1}^{m_t} y_{tj}$, and $\hat{\omega}_t = \frac{n_t/s_{1t}^2}{n_t/s_{1t}^2 + m_t/s_{2t}^2}$, with s_{1t}^2 and s_{2t}^2 being the sample variances of $(\hat{y}_{t1}, \dots, \hat{y}_{tn_t})$ and $(y_{t1}, \dots, y_{tm_t})$, respectively. The following test statistic can be used to test hypotheses (Eq. 12):

$$\tilde{T} = \frac{\hat{\mu}_{GDA} - \hat{\mu}_{GDB}}{\sqrt{\widehat{Var}(\hat{\mu}_{GDA}) + \widehat{Var}(\hat{\mu}_{GDB})}} \quad (15)$$

where

$$\widehat{Var}(\hat{\mu}_{GDt}) = \frac{1}{n_t/s_{1t}^2 + m_t/s_{2t}^2} \left[1 + 4\hat{\omega}_t(1 - \hat{\omega}_t) \left(\frac{1}{n_t - 1} + \frac{1}{m_t - 1} \right) \right]$$

is an exact expression of the variance of $\widehat{Var}(\hat{\mu}_{GDt})$ in the form of an infinite series.^[18] Thus, an approximate 100(1 - α)% confidence interval of $\mu_1 - \mu_2$ is given as

$$\left(\hat{\mu}_{GDA} - \hat{\mu}_{GDB} - z_{\alpha/2} \sqrt{\widehat{V}_T}, \hat{\mu}_{GDA} - \hat{\mu}_{GDB} + z_{\alpha/2} \sqrt{\widehat{V}_T} \right), \quad (16)$$

where $\widehat{V}_T = \widehat{Var}(\hat{\mu}_{GDA}) + \widehat{Var}(\hat{\mu}_{GDB})$. Therefore, the null hypothesis H_0 will be rejected if the above confidence interval does not contain 0.

Analysis for Category III and IV Designs

In this section, we will discuss the statistical inference for Category III and IV designs. For a Category III design, the study objectives at different stages are different (e.g., dose selection at Stage 1 vs. efficacy confirmation at Stage 2), whereas the study endpoints are the same at different stages. For a Category IV design, both study objectives and endpoints at different stages are different (e.g., dose selection using surrogate endpoint at Stage 1 vs. efficacy confirmation with clinical endpoint at Stage 2).

Let us consider a seamless phase II/III adaptive design. We suppose a surrogate (biomarker) endpoint and a well-established clinical endpoint are available for the treatment effect assessment. For comparing k treatments groups, $E_1, \dots, E_k$, with a control group C , let θ_i and ψ_i , $i = 1, \dots, k$, be the treatment effect assessed by the surrogate (biomarker) endpoint and the clinical endpoint for comparing E_i with C , respectively. Hence, the following hypothesis can be adopted to test the treatment effect using the surrogate (biomarker) endpoint:

$$H_{0,1}: \theta_1 = \dots = \theta_k, \quad (17)$$

whereas the hypothesis

$$H_{0,2}: \psi_1 = \dots = \psi_k \quad (18)$$

is used for testing the treatment effect with the clinical endpoint.

In practice, the investigators may have one or more interim analyses at each stage under a Category III or IV design. Cheng and Chow^[19] considered a seamless phase II/III adaptive design with two interim analyses at Stage 2 (phase III) and assumed that ψ_i is a monotone increasing function of the corresponding θ_i . The hypotheses (17) and (18) will be tested at four critical milestone points (i.e., end of Stage 1 analysis, Stage 2a analysis, Stage 2b analysis, and final analysis) based on accrued data. Their proposed tests are briefly described next. For simplicity, the variances of the surrogate (biomarker) endpoint and the clinical outcome are assumed to be known and denoted by σ^2 and τ^2 .

End of Stage 1 analysis—At Stage 1, $(k + 1)n_1$ subjects are randomized to either one of the k treatment arms or the control arm at a 1:1 ratio with n_1 subjects in each group. At the end of Stage 1 analysis, the most effective treatment will be selected compared to the control based on the surrogate endpoint. The selected treatment group along with the control group will then proceed to the subsequent stage. For pairwise comparison, Cheng and Chow^[19] considered test statistics $\hat{\theta}_{i,1}$, $i = 1, \dots, k$ and $S = \arg \max_{1 \leq i \leq k} \hat{\theta}_{i,1}$ (i.e., the arguments of the maxima for the test statistics $\hat{\theta}_{i,1}$, $i = 1, \dots, k$). In this case, if $\hat{\theta}_{S,1} \leq c_1$ for some prespecified critical value c_1 , then the trial is stopped for futility and we are in favor of $H_{0,1}$; and if $\hat{\theta}_{S,1} > c_{1,1}$ for a prespecified critical value $c_{1,1}$, the treatment E_S is selected to be the most promising treatment among the k treatments. Only those subjects who receive either the promising treatment or the control will be followed for the clinical endpoint. All other subjects will undergo necessary safety monitoring without treatment assessment.

Stage 2a analysis—At Stage 2a, $2n_2$ additional subjects are equally assigned to receive either the treatment E_S or the control C . The Stage 2a analysis is planned when the surrogate endpoint measures from $2n_2$ Stage 2 subjects and the clinical endpoint measures from $2n_1$ Stage 1

subjects who receive either the treatment E_s or the control C become available. Let us denote $T_{1,1} = \hat{\theta}_{s,1}$ and $T_{1,2} = \hat{\psi}_{s,1}$ as the test statistics from Stage 1 based on the surrogate endpoint and the primary endpoint, respectively. Let $\hat{\theta}_{s,2}$ be the test statistic based on the surrogate endpoint from Stage 2. We define

$$T_{2,1} = \sqrt{\frac{n_1}{n_1 + n_2}} \hat{\theta}_{s,1} + \sqrt{\frac{n_2}{n_1 + n_2}} \hat{\theta}_{s,2} \quad (19)$$

If $T_{2,1} \leq c_{2,1}$ for a prespecified critical value $c_{2,1}$, then we accept $H_{0,1}$ and stop the trial for futility; if $T_{2,1} > c_{2,1}$ and $T_{1,2} > c_{1,2}$, then we reject both $H_{0,1}$ and $H_{0,2}$, and stop the trial for efficacy; otherwise, if $T_{2,1} > c_{2,1}$ but $T_{1,2} \leq c_{1,2}$, then we will move on to Stage 2b.

Stage 2b analysis—At Stage 2b, no additional subjects will be recruited. The Stage 2b analysis will be performed when $2n_2$ Stage 2a subjects receive their clinical endpoint assessment. Let

$$T_{2,2} = \sqrt{\frac{n_1}{n_1 + n_2}} \hat{\psi}_{s,1} + \sqrt{\frac{n_2}{n_1 + n_2}} \hat{\psi}_{s,2}, \quad (20)$$

where $\hat{\psi}_{s,2}$ is the test statistic from Stage 2b. We will reject $H_{0,2}$ and stop the trial for efficacy if $T_{2,2} > c_{2,2}$ for a prespecified critical value $c_{2,2}$. Otherwise, we continue the enrollment to reach the prespecified number of subjects.

Final analysis—We will recruit $2n_3$ additional subjects and follow them till their primary clinical endpoints; then the final analysis will be performed. Let

$$T_3 = \sqrt{\frac{n_1}{n_1 + n_2 + n_3}} \hat{\psi}_{s,1} + \sqrt{\frac{n_2}{n_1 + n_2 + n_3}} \hat{\psi}_{s,2} + \sqrt{\frac{n_3}{n_1 + n_2 + n_3}} \hat{\psi}_{s,3}, \quad (21)$$

where $\hat{\psi}_{s,3}$ is the test statistic based on $2n_3$ additional subjects. If $T_3 > c_3$ for a prespecified critical value c_3 , then we will reject $H_{0,2}$ and declare efficacy; otherwise, accept $H_{0,2}$.

In the above design, all the parameters, $n_1, n_2, n_3, c_1, c_{1,1}, c_{2,1}, c_{2,2}$, and c_3 are determined such that an overall type I error rate of at a prespecified level of significance α will be controlled with a target power of $1 - \beta$. Note that the most promising treatment is selected based on the surrogate data rather than assessing $H_{0,2}$ at Stage 1. In other words, a dose does not need to be significant upon completion of Stage 1 in order to move forward.

The above approach is essentially a group sequential procedure with treatment selection at interim. No additional adaptations are involved. Cheng and Chow^[19] discussed a sample size reestimation procedure within the above design framework. Assume that ψ and θ are correlated with a local linear relationship. This assumption is reasonable if we focus only on the values at a neighborhood of the most promising treatment E_s . Therefore, at

the end of Stage 2a, the treatment effect of the primary endpoint can be reestimated using

$$\hat{\delta}_s = \frac{\hat{\psi}_{s,1}}{\hat{\theta}_{s,1}} T_{2,1}.$$

Thus, the sample size for final analysis can be reestimated based on a modified treatment effect of the primary endpoint $\delta = \max\{\hat{\delta}_s, \delta_0\}$, where δ_0 is a minimal clinically relevant treatment effect. Let m be the reassessed sample size for final analysis based on δ . If $m \leq n_3$ (originally planned), then there is no modification for the procedure; if $m > n_3$, then m subjects (instead of n_3) per arm will be recruited. Such an adaptation allows to adjust the treatment effect of the clinical outcome with a validated relationship between the surrogate endpoint and the clinical outcome.

SAMPLE SIZE CALCULATION FOR TWO-STAGE SEAMLESS ADAPTIVE DESIGN

When we apply a two-stage seamless adaptive design clinical trial, one of the questions commonly asked is how to perform sample size calculation. For Category I designs, Chow and Chang^[14] described the methods based on individual p values. These methods, however, are not appropriate for Category II–IV designs. Chow and Tu^[3] derived formulas and/or procedures for sample size calculation for Category II designs with various data types including continuous, discrete (binary response), and time-to-event endpoints assuming a well-established relationship between the Stage 1 endpoint and the Stage 2 endpoint.

Let us consider the same settings in Section “Analysis of Category II Designs” and suppose we will test the hypotheses in Eq. (13). Thus, under the local alternative hypothesis $H_1: \mu_A - \mu_B = \delta \neq 0$, the required sample size for achieving a $1 - \beta$ power at the significance level of α satisfies

$$-z_{\alpha/2} + |\delta| / \sqrt{\text{Var}(\hat{\mu}_{GDA}) + \text{Var}(\hat{\mu}_{GDB})} = z_\beta.$$

If we let $m_t = \rho n_t$, where $t = A$ or B , and $n_B = \gamma n_A$. Therefore, the total sample size, denoted by N_T , is given by $N_T = (1 + \rho)(1 + \gamma)n_A$. Then, we solve n_A as

$$n_A = \frac{1}{2} UV \left(1 + \sqrt{1 + 8(1 + \rho) \frac{W}{U}} \right), \quad (22)$$

where $U = \frac{(z_{\alpha/2} + z_\beta)^2}{\delta^2}$, $V = \frac{\sigma_A^2}{\rho + r_A^{-1}} + \frac{\sigma_B^2}{\gamma(\rho + r_B^{-1})}$, and

$W = V^{-2} \left[\frac{\sigma_A^2}{r_A(\rho + r_A^{-1})^3} + \frac{\sigma_B^2}{\gamma^2 r_B(\rho + r_B^{-1})^3} \right]$, with $r_t = \beta_1^2 \tau_t^2 / \sigma_t^2$, $t = A$ or B .

For testing a superiority hypothesis $H_1: \mu_A - \mu_B = \delta_1 > \delta$, the required sample size to achieve a $1 - \beta$ power at the significance level of α satisfies

$$-z_\alpha + (\delta_1 - \delta) / \sqrt{\text{Var}(\hat{\mu}_{GD_A}) + \text{Var}(\hat{\mu}_{GD_B})} = z_\beta.$$

This gives

$$n_A = \frac{1}{2} V X \left(1 + \sqrt{1 + 8(1 + \rho) \frac{W}{X}} \right), \quad (23)$$

$$\text{where } X = \frac{(z_\alpha + z_\beta)^2}{(\delta_1 - \delta)^2}.$$

If one wants to test for equivalence with the local alternative hypothesis that $H_1: \mu_A - \mu_B = \delta_1$, where $|\delta_1| < \delta$. The required sample size to achieve $1 - \beta$ power with a significance level α satisfies

$$-z_\alpha + (\delta - \delta_1) / \sqrt{\text{Var}(\hat{\mu}_{GD_A}) + \text{Var}(\hat{\mu}_{GD_B})} = z_\beta.$$

Thus, n_A is given by

$$n_A = \frac{1}{2} V Y \left(1 + \sqrt{1 + 8(1 + \rho) \frac{W}{Y}} \right), \quad (24)$$

$$\text{where } Y = \frac{(z_\alpha + z_{\beta/2})^2}{(\delta - |\delta_1|)^2}.$$

Under Category II designs, formulas for sample size calculation for binary response and time-to-event endpoints can be similarly derived for testing equality, non-inferiority, superiority, and equivalence. For Category III and IV designs, however, the above derived formulas for sample size calculation should be modified for controlling the overall type I error at a prespecified level for achieving a target power.

CONCLUDING REMARKS

In summary, a two-stage seamless adaptive design can be attractive to investigators due to its potential efficiency, including reducing the lead time between two traditional studies (e.g., a phase II trial and a phase III study), saving subjects by combining data collected from both stages for a final analysis, and possibly making an early decision (e.g., stop the trial early for futility). Nonetheless, as mentioned earlier, to achieve the above advantages for implementing a two-stage seamless adaptive design, the investigators usually need to spend extra time on the planning stage. Hence, the overall time of a product development may be actually longer than adopting a traditional approach (i.e., two separated studies).

In practice, as discussed earlier, two-stage seamless adaptive designs can be classified into four categories based on the study objectives and the study endpoints used at different stages. In the case when the study objectives and/or the study endpoints are different at different stages, it is important to determine how to combine the data collected from both stages to perform the final analysis. It is also critical to know how the sample size calculation should be done for achieving a desired overall type I error rate with a target power to meet the study objectives originally set for the two stages (separate studies).

Chow and Chang^[14] expressed concerns that the standard statistical methods derived for a group sequential design trial with one planned interim analysis are often directly applied to a two-stage seamless adaptive design regardless of whether the study objectives and/or the study endpoints are the same at different stages. In many cases, especially when the study objectives and/or study endpoints at different stages are different, the obtained p -value and confidence interval for assessment of the treatment effect may not be correct or reliable with the direct application of standard statistical methods. Moreover, sample size obtained under a standard group sequential trial design may not be sufficient for achieving the study objectives under a two-stage seamless adaptive design. In practice, the major challenge for utilizing a two-stage seamless adaptive design is not only the development of valid statistical methods but also the development of a set of criteria for choosing the most appropriate design for valid and reliable assessment of test treatment under investigation. Sometimes, a traditional approach (i.e., two separated studies) is more promising.

Two-Stage Design: Phase II Cancer Clinical Trials

Sin-Ho Jung

Department of Biostatistics and Bioinformatics, Duke University, Durham, North Carolina, U.S.A.

Abstract

Phase II trials have been very widely conducted and published every year for cancer clinical research. Because of their small sample sizes, statistical methods based on large sample approximation are not appropriate for design and analysis of phase II trials. As a prospective clinical research, the analysis method of a phase II trial is predetermined at the design stage, and it is analyzed during and at the end of the trial as planned by the design. The analysis method of a trial should be matched with the design method. For two-stage, single-arm phase II trials, Simon's method has been the standard for choosing an optimal design, but the resulting data have been analyzed and published ignoring the two-stage design aspect with small sample sizes. In this article, we review the analysis methods that exactly get along with the exact two-stage design method. We also discuss some statistical methods to improve the existing design and analysis methods for single-arm, two-stage phase II trials.

Keywords: Accrual overrun; Admissible design; Confidence interval; P -value; Two-stage design; Uniformly minimum unbiased estimator.

INTRODUCTION

Cancer clinical trials are to investigate the efficacy and toxicity of experimental cancer therapies. If an appropriate dose level of an experimental drug is determined from a phase I trial, the drug's anticancer activity is assessed through phase II clinical trials. Phase II clinical trials are to screen out inefficacious experimental therapies before they proceed to further investigation through large-scale phase III trials. In order to expedite this process, phase II trials traditionally use a single-arm design to treat patients by experimental therapies only. So, the efficacy of an experimental therapy is compared with that of a standard therapy that is called a historical control. The most popular primary endpoint of phase II cancer clinical trials is tumor response that is measured by the change in tumor size before and during treatment. For a solid tumor, if the size, defined as the sum of the largest diameters of the target tumors, decreases by at least 30% compared to that at the baseline, we call it a partial response by RECIST 1.1.^[1] If the target tumor disappears during treatment, we call it a complete response (CR). Overall response is defined as partial response or CR.

Phase II trials generally require shorter study periods than phase III trials. Consequently, phase II trials have small sample sizes, so that exact statistical methods are preferable to the asymptotic methods for their design and analysis. Various exact methods have been published for phase II trials with binary outcomes such as tumor response. For ethical reasons, two-stage designs

are commonly used for phase II cancer clinical trials. A typical single-arm, two-stage trial with a futility stopping value (a_1), a superiority stopping value (b_1), and a stage 2 rejection value (a) is conducted as follows:

- Stage 1: Treat n_1 patients and count the number of responders X_1 .
 - If $X_1 \leq a_1$, then reject the experimental therapy and stop the trial.
 - If $X_1 \geq b_1$, then accept the experimental therapy and stop the trial.
 - If $a_1 < X_1 < b_1$, then proceed to the second stage.
- Stage 2: Treat an additional n_2 patients and count the number of responders X_2 .
 - If $X_1 + X_2 \leq a$, then reject the experimental therapy.
 - Otherwise, accept the experimental therapy for further investigation.

We usually do not stop the trial early for superiority since there is no ethical issue to continue treating patients with an efficacious therapy, and we want to collect as many data as possible to use when designing a subsequent phase III trial. In this case, we choose $b_1 = n_1 + 1$.

The design and analysis of phase II trials require exact statistical methods accounting for two-stage design and small sample sizes. The most popular for phase II cancer clinical trials has been a two-stage design with a futility stopping only based on Simon's^[2] minimax or optimality criterion.^[3–5] But most publications reporting the results of phase II trials fail to appropriately address these issues.

When the aforementioned two-stage phase II trial is completed, we should be able to accept or reject the experimental therapy based on the critical values and sample sizes (a_1, b_1, a, n_1, n_2) . In a usual clinical trial, we would recruit slightly more patients than required to make up for possible attrition due to ineligibility and dropout. As a result, the observed sample size tends to be different from that specified by the design. In a typical two-stage phase II trial, the sample size at the stopping stage is different from (usually larger, but rarely smaller, than) the planned one. In this case, the critical values at the stopping stage become meaningless. This may be the major reason why investigators do not make clear conclusions from their phase II trials. Addressing this issue, we propose to extend the two-stage testing rule by calculating a p -value or a confidence interval of the true response rate (RR). These methods exactly coincide with the two-stage testing rule if the observed sample sizes are identical to the prespecified (n_1, n_2) . In this article, we discuss further design and analysis methods for single-arm phase II trials with tumor response as the primary endpoint. We further extend Simon's criteria to search for an alternative two-stage design.

OPTIMAL TWO-STAGE DESIGNS

In this section, we focus on the popular two-stage designs with a futility interim test only, i.e., $b_1 = n_1 + 1$. These designs are defined by the number of patients to be treated, n_1 and n_2 , during stages 1 and 2, and rejection values, a_1 and a ($a_1 < a$), so that we specify them by $(a_1/n_1, a/n)$, where $n = n_1 + n_2$ is called the maximal sample size. The values of $(a_1/n_1, a/n)$ are determined based on some prespecified design parameters as described next. Let p_0 denote the maximum unacceptable probability of response which is usually chosen by the RR of a historical control, and p_1 the minimum acceptable probability of response with $p_0 < p_1$. For the true RR p of the experimental therapy, we want to test $H_0: p \leq p_0$ against $H_1: p > p_0$. In this statistical testing, rejecting H_0 means accepting the experimental therapy. Given (p_0, p_1) , we can calculate the type I error probability α and power $1 - \beta$ of a two-stage design $(a_1/n_1, a/n)$ based on the fact that the number of responders from the two stages, X_1 and X_2 , are independent binomial random variables.

Suppose that we want to find a two-stage design with a type I error probability no larger than α^* and a power no smaller than $1 - \beta^*$ for given (p_0, p_1) values. We call $(p_0, p_1, \alpha^*, \beta^*)$ design parameters. Given (p_0, p_1) , there are infinitely many two-stage designs satisfying the $(\alpha^*, 1 - \beta^*)$ constraint. Noting that the sample size of a two-stage trial is a random variable taking n_1 or n , we can calculate the expected sample size of the trial given a true RR of the experimental therapy. Simon^[2] proposes two criteria to select a good two-stage design among these candidate designs. The minimax design minimizes the maximal sample size, n , among the designs satisfying the $(\alpha^*, 1 - \beta^*)$ constraint. On the other

hand, the so-called optimal design minimizes the expected sample size under $H_0: p = p_0$, denoted as EN.

Although the minimax and optimal designs have both been widely used for long, other two-stage designs have been largely ignored in the past. Oftentimes, the two Simon's criteria result in very different two-stage designs, i.e., the minimax design may have an excessively large EN compared to the optimal design and the optimal design may have an excessively large maximal sample size n compared to the minimax design. This results from the discrete nature of the exact binomial method.

Example 1

For the design parameters $(p_0, p_1, \alpha^*, 1 - \beta^*) = (0.1, 0.3, 0.05, 0.85)$, the minimax design is given by $(a_1/n_1, a/n) = (2/18, 5/27)$ and the optimal design by $(1/11, 6/35)$. The maximal sample size n for the minimax design is less than that for the optimal design by $8(=35-27)$. However, the expected sample size EN under H_0 for the optimal design is 18.3, which is only slightly smaller than $EN = 20.4$ for the minimax design. We may consider choosing the minimax design since, compared to the optimal design, it largely saves the maximal sample size while sacrificing the expected sample size by only about $2(=20.4-18.3)$.

In this case, however, there exists a practical compromise without changing the statistical operating characteristics appreciably.

Example 1 (revisited)

For the same design parameters $(p_0, p_1, \alpha^*, 1 - \beta^*) = (0.1, 0.3, 0.05, 0.85)$, the design given by $(a_1/n_1, a/n) = (1/13, 5/28)$ requires only one more patient in the maximal sample size n than the minimax design, but its expected sample size EN under H_0 is very comparable to that of the optimal design (18.7 vs 18.3).

This design is a good compromise between the minimax design and the optimal design.^[6] There can be multiple compromising designs. Jung et al.^[7] show that they are admissible designs in terms of the loss function combining the maximal sample size and the expected sample size under H_0 . Simon's minimax and optimal designs belong to the family of admissible designs too. An interactive computer program to find admissible designs is available in www.dukecancerinstitute.org/research/shared-resources/biostatistics/clinical-trial-design-systems/.

Figure 1 is a snapshot of this program for Example 1. It displays the plot of EN against n for various designs with $n \leq 37$. Simon's minimax design given by $(a_1/n_1, a/n) = (2/18, 5/27)$ is shown at the leftmost in the figure and the optimal design given by $(1/11, 6/35)$ is shown at the very bottom. The program provides the specification of a design $(a_1/n_1, a/n)$ along with $(\alpha, 1 - \beta)$, EN, and the probabilities of early termination for $p = p_0$ and p_1 when the circle representing a candidate design, actually (n, EN) , is clicked with a pointer.

In this section, we have considered two-stage designs with a futility stopping value only. Chang et al.^[8] propose optimal multistage designs with both futility and superiority stopping boundaries by minimizing the average of expected sample sizes under H_0 and H_1 . Mander et al.^[9] extends the admissible design concept to multistage designs with both futility and superiority stopping

Fig. 1 Two-stage designs for $(p_0, p_1, \alpha^*, \beta^*) = (0.1, 0.3, 0.05, 0.15)$ with $N = 37$

boundaries by using a loss function combining the maximal sample size, the expected sample size under H_0 , and the expected sample size under H_1 . Englert and Kieser^[10] propose optimal adaptive two-stage designs whose stage 2 sample sizes are determined based on the number of responders from stage 1. They do not consider early stopping. Accounting for uncertainty of the true treatment effect, Kieser^[11] proposes to specify an interval of possible true RR in designing a two-stage design.

INFERENCE ON RR

Estimation of RR

In a two-stage phase II trial, let M ($=1$ or 2) denote the stopping stage, and S the cumulative number of responders in the stopping stage, i.e., $S = X_1$ if $M = 1$ and $S = X_1 + X_2$ if $M = 2$. The most popular estimator of RR p for $(M, S) = (m, s)$ is the sample proportion:

$$\hat{p} = \begin{cases} s/n_1 & \text{if } m = 1 \\ s/(n_1 + n_2) & \text{if } m = 2 \end{cases}$$

By not reflecting the two-stage design aspect of the trial, this estimator, called the maximum likelihood estimator (MLE), is always negatively biased for standard two-stage trials with

futility stopping only.^[12] As a result, if p_0 of a future trial is chosen by the sample proportion of a historical control taken from a previous two-stage phase II trial, then it will underestimate the true RR of the historical control and result in a higher chance of false positivity for the future trial.

For $(M, S) = (m, s)$, the uniformly minimum-variance unbiased estimator (UMVUE) of p for two-stage phase II trials is given by

$$\tilde{p} = \begin{cases} s/n_1 & \text{if } m = 1 \\ \frac{\sum_{x_1=(a_1+1) \vee (s-n_2)}^{s \wedge (b_1-1)} \binom{n_1-1}{x_1-1} \binom{n_2}{s-x_1}}{\sum_{x_1=(a_1+1) \vee (s-n_2)}^{s \wedge (b_1-1)} \binom{n_1}{x_1} \binom{n_2}{s-x_1}} & \text{if } m = 2 \end{cases} \quad (1)$$

where $a \wedge b = \min(a, b)$, $a \vee b = \max(a, b)$, $\binom{m}{k} = m! / \{k!(m-k)!\}$, and $x! = x(x-1) \times \cdots \times 2 \times 1$ [12]. Note that the UMVUE and the MLE are identical if the trial stops after stage 1, i.e., $m = 1$.

For a true RR of p , the probability mass function (PMF) of (M, S) , $f(m, s|p) = \Pr(M = m, S = s)$, is given as^[12]

$$f(m, s|p) = \begin{cases} p^s (1-p)^{n_1-s} \binom{n_1}{s} & \text{if } m = 1, 0 \leq s \leq a_1 \text{ or } b_1 \leq s \leq n_1 \\ p^s (1-p)^{n_1+n_2-s} \sum_{x_1=a_1+1}^{(b_1-1) \wedge s} \binom{n_1}{x_1} \binom{n_2}{s-x_1} & \text{if } m = 2, a_1+1 \leq s \leq b_1-1+n_2 \end{cases} \quad (2)$$

Since the UMVUE of p is a function of (M, S) , its PMF is derived from $f(m, s|p)$.

Example 2

Under $(p_0, p_1, \alpha^*, 1 - \beta^*) = (0.2, 0.4, 0.05, 0.8)$, the Simon's optimal two-stage design with a futility stopping value only is given as $(a_1/n_1, a/n) = (3/13, 12/43)$. Table 1 gives the UMVUE and MLE for observations (m, s) and their PMF for various RR values in the two-stage design. When $m = 1$, two estimates are exactly the same as noted earlier. When $m = 2$, the MLE is much smaller than the UMVUE for small s values. The UMVUE is shown to have a comparable variance compared to the MLE overall.^[12]

In order to account for ineligible or unevaluable patients, we often accrue slightly more (or possibly fewer) patients than the

planned sample size at the stopping stage, especially in multi-center trials.^[13,14] But this does not become any issue in the calculation of the UMVUE, since it does not require the specification of the critical values (a_m, b_m) at the stopping stage m , where $a_2 = a$ and $b_2 = a + 1$. If the study is terminated after stage 1 (i.e., $m = 1$), then the UMVUE is calculated by considering the observed number of stage 1 patients as n_1 . If the study is proceeded to the second stage (i.e., $m = 2$), then the UMVUE in Eq. 1 depends only on the rejection values for stage 1 (a_1, b_1) and the number of patients for the two stages (n_1, n_2) . When $m = 2$, the interim test is always conducted using (a_1, b_1) when exactly n_1 patients have response data as planned. However, the number of stage 2 patients may be slightly different from n_2 . In this case, we calculate the UMVUE by considering the observed number of stage 2 patients as n_2 with (n_1, a_1, b_1) fixed by the design.

Table 1 UMVUE, MLE, and PMF for true p for each observation in a two-stage design with $(a_1/n_1, a/n) = (3/13, 12/43)$

Example 2 (revisited)

Suppose that a phase II trial was designed for the Simon's optimal two-stage design with a futility stopping value only given as $(a_1/n_1, a/n) = (3/13, 12/43)$ under $(p_0, p_1, \alpha^*, 1 - \beta^*) = (0.2, 0.4, 0.05, 0.8)$, but it was completed with $s=7$ responders from a total of 45 patients after stage 2. Then, by using $(a_1, n_1) = (3, 13)$ and conditioning n_2 at $32 (= 45 - 13)$, we have $(a_1 + 1) \vee (s - n_2) = (3 + 1) \vee (7 - 32) = 4$ and $s \wedge (b_1 - 1) = 7 \wedge (14 - 1) = 13$. Hence, from Eq. 1, the UMVUE is calculated by

$$\tilde{p} = \frac{\sum_{x_1=4}^7 \binom{12}{x_1-1} \binom{32}{7-x_1}}{\sum_{x_1=4}^7 \binom{13}{x_1} \binom{32}{7-x_1}} = \frac{1,362,988}{4,241,380} = 0.321$$

whereas the MLE is only $\hat{p} = 7/45 = 0.156$.

Bowden and Wason^[15] investigate various estimators of RR including the UMVUE and compare their performance.

Confidence Interval

Jung and Kim^[12] prove that the ordering of the sample space for (M, S) in terms of the magnitude of the UMVUE is identical to that proved by Jennison and Turnbull^[16] (see also Armitage^[17]; Tsiatis et al.^[18]). In other words, we have

$$\begin{aligned} &\tilde{p}(1,0) < \tilde{p}(1,1) < \cdots < \tilde{p}(1,a_1) \\ &< \tilde{p}(2,a_1+1) < \cdots < \tilde{p}(2,b_1-1+n_2) \\ &< \tilde{p}(1,b_1) < \cdots < \tilde{p}(1,n_1) \end{aligned} \quad (3)$$

where $\tilde{p}(m,s)$ denotes the UMVUE for $(M, S) = (m, s)$. Hence, the confidence intervals calculated by Clopper and Pearson^[19] and the stochastic ordering based on the magnitude of the UMVUE are identical to those by Jennison and Turnbull.^[16]

With the UMVUE $\tilde{p}(m,s)$, an exact $100(1 - \alpha)\%$ equal tail confidence interval (p_L, p_U) for p is given by

$$\Pr(\tilde{p}(M,S) \geq \tilde{p}(m,s) | p = p_L) = \alpha/2$$

and

$$\Pr(\tilde{p}(M,S) \leq \tilde{p}(m,s) | p = p_U) = \alpha/2,$$

where the probabilities are calculated using the PMF of (M, S) as defined in Eq. 2. Confidence limits p_L and p_U can be obtained by solving the equations using a numerical method such as the bisection method, which can be described to solve an equation $g(x) = 0$ as follows:

- Find an interval $[x_1, x_2]$ such that $g(x_1)g(x_2) < 0$.
- For $x_3 = (x_1 + x_2)/2$,
 - If $g(x_1)g(x_3) < 0$, then $x_3 \rightarrow x_2$.
 - Otherwise, $x_3 \rightarrow x_1$.
- Continue (B) until $|x_1 - x_2|$ is small enough and choose x_3 as the solution to the equation.

Example 3

Suppose that we observed $(m,s)=(2,7)$ from a two-stage study with lower boundaries only, $(n_1, n_2, a_1, a) = (13, 30, 3, 12)$. In this case, we have $b_1 = n_1 + 1 = 14$, $(a_1 + 1) \vee (s - n_2) = (3 + 1) \vee (7 - 30) = 4$, and $s \wedge (b_1 - 1) = 7 \wedge (14 - 1) = 7$. From Eq. 1, the UMVUE is

$$\tilde{p}(2, 7) = \frac{\sum_{x_1=4}^7 \binom{13-1}{x_1-1} \binom{30}{7-x_1}}{\sum_{x_1=4}^7 \binom{13}{x_1} \binom{30}{7-x_1}} = .322.$$

Using Eq. 2, we have

$$\Pr(\tilde{p}(M, S) \geq .322 | p = .103) = .025$$

and

$$\Pr(\tilde{p}(M, S) \leq .322 | p = .538) = .025$$

so that a 95% confidence interval on p is given as (0.103, 0.538), which is the same as the one according to Jennison and Turnbull.^[16] In contrast, a naive exact 95% confidence interval calculated by Clopper and Pearson^[19] ignoring the two-stage aspect of the study design is given as (0.068, 0.307). Note that the latter is narrower than the former by ignoring the group sequential feature of the study. Furthermore, the former is slightly shifted to the right from the latter to reflect the fact that the study has been continued to stage 2 after observing more responders than $a_1 = 3$ in stage 1. The popularly used asymptotic confidence interval $\hat{p} \pm 1.96 \sqrt{\hat{p}(1-\hat{p})/n} = (.052, .273)$ with 95% significance level is even narrower and further shifted to the left than the naive exact confidence interval.

The Jennison–Turnbull confidence interval based on the stochastic ordering (Eq. 3) has a desirable property: given (p_0, α^*) , the testing result based on the two-stage design $(a_1/n_1, a/n)$ exactly coincides with that based on the one-sided confidence interval with a significance level of $100(1 - \alpha^*)\%$, i.e., we reject $H_0 : p = p_0$ by the two-stage design if and only if the lower confidence limit is larger than p_0 . This property is very valuable especially when the observed sample size for the stopping stage is different from the sample size specified by the study design. In this case, the two-stage design does not provide us a proper testing rule any more since the rejection values, (a_1, b_1) or a , are meaningful only when the number of patients are identical to the prespecified sample size. But we can calculate a Jennison–Turnbull confidence interval of RR by treating the observed sample size at the stopping stage like the planned sample size. This is possible since Eqs. 2 and 3 do not require specification of the rejection values at the stopping stage. Various confidence interval methods have been proposed for multistage designs,^[20,21] but no other confidence intervals have this property.

Example 4

Kim et al.^[22] published a phase II trial of concurrent chemoradiotherapy for newly diagnosed patients with limited-stage extranodal natural killer/T-cell lymphoma, nasal type. The primary endpoint is the CR rate. The study had the Simon's optimal two-stage design $(a_1/n_1, a/n) = (4/6, 22/27)$ under $(p_0, p_1, \alpha^*, 1 - \beta^*) = (0.7, 0.9, 0.05, 0.8)$. The trial proceeded to the second stage to treat a total of 30 eligible and evaluable patients of which 27 achieved CR. Since the observed maximal sample size is different from the planned one, the rejection value $a = 22$ was of no use to determine the positivity of the study. The authors

concluded the study to be positive without statistical ground. Noting this, Shimada and Suzuki^[23] claimed that this trial was a negative study by calculating an asymptotic confidence interval with two-sided 95% significance level and showing that it covers $p_0 = 0.7$. This claim is misleading since their interval (i) has a two-sided $100(1 - \alpha^*) = 95\%$ confidence level while the two-stage design has 1-sided $\alpha^* = 5\%$, (ii) ignores the two stage feature of the trial, and (iii) is using a large-sample approximation. Kim et al.^[24] defended their conclusion by showing that the 1-sided 95% Jennison–Turnbull confidence interval (0.762, 1] is above $p_0 = 0.7$.

P-VALUE CALCULATION

Through a phase II trial, we intend to conduct a statistical testing to reject or accept its experimental therapy. If we reject or fail to reject the null hypothesis, we should be able to provide a p -value as a measure of how strong evidence the decision is based on against the null hypothesis. However, publications from phase II trials rarely report p -values to support their conclusions. In most of the publications, it is not even clear if the investigators conclude to accept their therapies or not.

Using the stochastic ordering of UMVUE (Eq. 3), Jung et al.^[25] propose a p -value method for two-stage phase II clinical trials. Noting that a p -value is defined as the probability to observe an extreme test statistic value toward the direction of H_1 when H_0 is true, they propose to calculate the probability to observe a UMVUE value larger than that obtained from the study under H_0 . Let $\tilde{p}$ denote the UMVUE of the RR observed from a two-stage phase II trial specified by (a_1, b_1, a, n_1, n_2) . Given $(M, S) = (m, s)$, the p -value = $\Pr\{\tilde{p}(M, S) \geq \tilde{p}(m, s) | p_0\}$ based on UMVUE can be calculated as

$$p\text{-value} = \begin{cases} \sum_{j=8}^{n_1} f(1, j | p_0) & \text{if } m = 1, s \geq b_1 \\ 1 - \sum_{j=0}^{s-1} f(1, j | p_0) & \text{if } m = 1, s \leq a_1 \\ \sum_{j=b_1}^{n_1} f(1, j | p_0) + \sum_{j=8}^{b_1-1+n_2} f(2, j | p_0) & \text{if } m = 2 \end{cases} \quad (4)$$

Jung et al.^[25] show that, if the observed sample size at each stage is identical to that specified by the design, the decision by the two-stage design exactly matches with that by the p -value compared with the α^* value. As discussed in the previous section, the confidence interval calculated by Jennison and Turnbull^[16] has this property, too.

Example 5

For $H_0 : p_0 = 0.4$ vs. $H_1 : p_1 = 0.6$, the two-stage design $(n_1, n_2, a_1, b_1, a) = (34, 5, 17, 35, 20)$ is the Simon's minimax design among those with $(\alpha^*, 1 - \beta^*) = (0.05, 0.8)$ and a futility

Table 2 UMVUE, MLE, and p -values using these estimators for a two-stage design of $(n_1, n_2, a_1, b_1, a) = (34, 5, 17, 35, 20)$ with $p_0 = 0.4$

Traditional
(cont.)-Z-Score

stopping boundary only. Table 2 displays the p -values and the PMF at $p_0 = .4$ for each sample point in the descending order for UMVUE. For example, for $(m, s) = (2, 19)$, we calculate the UMVUE by

$$\begin{aligned}\tilde{p} &= \frac{\sum_{x_1=(17+1)\vee(19-5)}^{19\wedge(35-1)} \begin{pmatrix} 34-1 \\ x_1-1 \end{pmatrix} \begin{pmatrix} 5 \\ 19-x_1 \end{pmatrix}}{\sum_{x_1=(17+1)\vee(19-5)}^{19\wedge(35-1)} \begin{pmatrix} 34 \\ x_1 \end{pmatrix} \begin{pmatrix} 5 \\ 19-x_1 \end{pmatrix}} \\ &= \frac{\begin{pmatrix} 33 \\ 17 \end{pmatrix} \begin{pmatrix} 5 \\ 1 \end{pmatrix} + \begin{pmatrix} 33 \\ 18 \end{pmatrix} \begin{pmatrix} 5 \\ 0 \end{pmatrix}}{\begin{pmatrix} 34 \\ 18 \end{pmatrix} \begin{pmatrix} 5 \\ 1 \end{pmatrix} + \begin{pmatrix} 34 \\ 19 \end{pmatrix} \begin{pmatrix} 5 \\ 0 \end{pmatrix}} = 0.5337.\end{aligned}$$

Hence, when $(m, s) = (2, 19)$ is observed, we calculate the p -value based on UMVUE as

$$\begin{aligned}\Pr(\tilde{p}(M, S) \geq .5337 | p_0) &= \sum_{j=19}^{39} f(2, j | p_0) \\ &= .0129 + .0219 + .0217 + .0145 + .0075 + .0033 + .0013 \\ &\quad + .0005 + .0002 + .0000 + \dots + .0000 \\ &= 0.838.\end{aligned}$$

Since $p\text{-value} > \alpha^* (=0.05)$, we fail to reject H_0 . Since $s = 19$ after stage 2 ($=m$) is smaller than $a = 20$, we fail to reject H_0 by the two stage testing rule too. Table 2 reports the p -values based on the ordering by MLE values and the p -values calculated by ignoring the fact that the two-stage design aspect, denoted as “naive.” Note that the p -values based on UMVUE and MLE orderings are different for large s values with $m = 1$ and for small s values with $m = 2$. This occurs because of the difference between the UMVUE ordering and the MLE ordering for the small s values with $m = 2$. The naive p -values are quite different from the p -values based on the UMVUE ordering too.

The strength of the above p -value method is that it can be extended to the cases where the observed sample size at the stopping stage is different from that specified by the design. This becomes possible because the PMF $f(m, s | p)$ and the UMVUE depend on the stopping boundaries only up to stage $m - 1$, i.e., $\{(a_k, b_k), 1 \leq k \leq m - 1\}$, where $a_2 = b_2 - 1$ denotes a , the rejection value at the second stage. Suppose that a study stopped after stage $m = 1$ with $S = s$ responders from n_1 patients that may be different from the stage 1 sample size specified by the design. Then, Eq. 4 can be modified to calculate a p -value:

$$p\text{-value} = \begin{cases} \sum_{j=s}^{n_1} p^s (1-p)^{n_1-s} \begin{pmatrix} n_1 \\ s \end{pmatrix} & m=1 \text{ and the study} \\ & \text{is stopped for superiority} \\ 1 - \sum_{j=0}^{s-1} p^s (1-p)^{n_1-s} \begin{pmatrix} n_1 \\ s \end{pmatrix} & m=1 \text{ and the study} \\ & \text{is stopped for futility} \end{cases}.$$

Note that the p -value with $m = 1$ is calculated as if the study had a single-stage design with sample size n_1 , so that it does not require specification of stopping values (a_1, b_1) .

On the other hand, suppose that the study proceeded to the second stage, i.e., $m = 2$. In this case, the stage 1 decision will be made based on (a_1, b_1, n_1) as specified by the design, but the sample size for the second stage may be slightly different from n_2 that is specified by the design. In this case, based on the observed values of (n_2, s) , we calculate

$$\begin{aligned}p\text{-value} &= \sum_{j=b_1}^{n_1} p^s (1-p)^{n_1-s} \begin{pmatrix} n_1 \\ s \end{pmatrix} \\ &\quad + \sum_{j=s}^{b_1-1+n_2} p^s (1-p)^{n_1+n_2-s} \sum_{x_1=a_1+1}^{(b_1-1)\wedge s} \begin{pmatrix} n_1 \\ x_1 \end{pmatrix} \begin{pmatrix} n_2 \\ s-x_1 \end{pmatrix}\end{aligned}$$

when $m = 2$. This p -value does not require specification of a either. We can reject H_0 and accept the study therapy when $p\text{-value} < \alpha^*$ regardless of the observed sample size at the stopping stage.

It is easy to show that the ordering of MLE depends on the critical values at the stopping stage. Hence, we cannot calculate an MLE-based p -value if the sample size at the stopping stage is different from that specified by the design. Furthermore, the decision rule based on the MLE-based p -value may not match that based on the two-stage testing rule irrespective of whether the observed sample is identical to the planned one.

Example 4 (revisited)

In Example 4, with 27 CRs out of $n = 30$ patients after the second stage, the p -value is 0.0086 by the above method for $p_0 = 0.7$ and $(a_1, n_1) = (4, 6)$. Since $p\text{-value} < \alpha^*$, this is another justification that the study by Kim et al.^[22] is a positive study. For $\alpha^* = 0.05$, this study will be positive with 26 CRs ($p\text{-value} = 0.0259$), but not with 25 CRs ($p\text{-value} = 0.0605$).

As mentioned previously, the critical values of a two-stage design cannot be used for testing if the realized sample size at the stopping stage is different from that specified by the design. In this case, we can conduct a statistical testing by calculating the p -value with the sample size at the stopping stage conditioned on the observed value and checking if it is smaller than the prespecified α level. In the previous section, we show that the Jennison–Turnbull confidence interval can be used for this purpose too. This property makes the p -value, together with the Jennison–Turnbull confidence interval, very useful for the analysis of two-stage phase II trials. Other p -value methods for multistage design^[26,27] do not have these desirable properties.

Green and Dahlberg^[13] and Herndon^[14] have also considered under- or over-accrual of patients in each stage and proposed some ad hoc approaches to the selection of rejection values depending on the realized sample sizes. Chen and Ng^[28] considered a set of combinations for possible sample sizes for stages 1 and 2 (n_1, n_2) and provided the rejection values (a_1, a) to minimize the maximal sample size or the average expected sample, assuming that each combination in the set has the same probability to be observed. The latter approach seems to have some issues: (i) If the combination of realized sample sizes does not belong to the prespecified set, then it does not provide valid rejection values; and (ii) for each combination of (n_1, n_2) , rejection values (a_1, a) are given. For each n_1 value, there are multiple n_2 values with their own a_1 values. So, it is not clear which rejection value a_1

should be used for a realized n_1 after stage 1. Furthermore, suppose that we observed a combination (n_1, n_2) through two stages. Then, we will use a that is assigned to this combination, but a_1 that has been used after stage 1 may be different from the stage 1 rejection value assigned to this combination of sample sizes.

For $N_1 = n_1$ and $N_2 = n$, Chang and O'Brien^[29] use the likelihood ratio

$$\frac{f(m, s | \hat{p})}{f(m, s | p_0)} = \left(\frac{\hat{p}}{p_0} \right)^s \left(\frac{1 - \hat{p}}{1 - p_0} \right)^{N_m - s}$$

to measure how far the MLE $\hat{p} = \hat{p}(m, s)$ is from p_0 . Chang et al.^[30] and Cook^[31] use the likelihood ratio ordering to derive p -values from sequential tests. Note that the ordering of the sample space based on the likelihood ratio is two sided in nature, so that it is inappropriate for p -values for phase II trials which have one-sided hypotheses. It is obvious from Eq. 3 that the UMVUE gives p -values satisfying the properties: (i) the p -values in the acceptance region of H_0 are larger than those in the rejection region, and (ii) the p -value for the critical value matches with the type I error probability of the sequential testing. These properties are not satisfied by p -values derived from other orderings.

Abstract

The Food and Drug Administration (FDA) is a U.S. government agency under the Department of Health and Human Services that is responsible for ensuring that the food we eat is safe, the cosmetics we use are pure and safe, and medicines and medical products are safe and effective for uses indicated in the product labels. This entry is dedicated to giving an overview of the FDA's history and role in American life.

INTRODUCTION

The Food and Drug Administration (FDA) is a U.S. government agency under the Department of Health and Human Services (DHHS) that plays a complex and important role in the lives of all Americans, as well as in the lives of consumers of many products grown, processed, and/or manufactured in the United States. As mandated by federal law, the FDA helps ensure that the food we eat is safe and wholesome, the cosmetics we use are pure and safe, and medicines and medical products are safe and effective for uses indicated in the product labels. The FDA is also responsible for overseeing veterinary medical and food products.

OVERVIEW

The FDA mission, formalized in the FDA Modernization Act of 1997, is as follows:

- To promote public health by promptly and efficiently reviewing clinical research and by taking appropriate action on the marketing of regulated products in a timely manner.
- With respect to such products, to protect public health by ensuring that foods are safe, wholesome, sanitary, and properly labeled; human and veterinary drugs are safe and effective; there is reasonable assurance of the safety and the effectiveness of devices intended for human use; cosmetics are safe and properly labeled; and public health and safety are protected from electronic product radiation.
- To participate through appropriate processes with representatives of other countries to reduce the burden of regulation, to harmonize regulatory requirements, and to achieve appropriate reciprocal arrangements.

- As determined to be appropriate by the Secretary [of DHHS], to carry out items (1) through (3) in consultation with experts in science, medicine, and public health, and in cooperation with consumers, users, manufacturers, importers, packers, distributors, and retailers of regulated products.

To accomplish these goals, the FDA is divided into six centers, along with a network of regional field offices (see [Fig. 1](#)). Three centers focus on human medical products: the Center for Biologics Evaluation and Research (CBER), the Center for Devices and Radiological Health (CDRH), and the Center for Drug Evaluation and Research (CDER). The Center for Food Safety and Applied Nutrition (CFSAN) is responsible for overseeing food and food products; the Center for Veterinary Medicine (CVM) enables the marketing of effective and safe veterinary medical products; and the National Center for Toxicological Research (NCTR) is a basic research facility that primarily studies problems related to the biological mechanisms underlying the toxicity of products faced by all of the centers with regulatory responsibilities.

The goal of this entry is to provide an overview of the FDA while discussing the role of statistics in drug regulation. While this discussion will be far from comprehensive, we will attempt to provide practical commentary regarding the interaction between the FDA and its customers. We will begin by discussing the origin of the FDA and the important historical events that shaped its current structure and purpose.

HISTORICAL DEVELOPMENT

The organization we know today has evolved via a long and interesting series of events, beginning in 1785 when

Fig. 1 Organizational structure of the FDA

the state of Massachusetts enacted the first food adulteration law in the United States. The FDA itself had its origins in the establishment of the Bureau of Chemistry in the Department of Agriculture in 1862 by President Abraham Lincoln. A national food and drug law was first recommended in 1880, but one was not enacted until 1906, following a flurry of congressional activity between 1879 and 1906 resulting in over 100 bills relating to the safety of food and drug products.

Three landmarks of food and drug law are the Biologics Control Act of 1902, and the Food and Drugs Act and the Meat Inspection Act, both of 1906. The first established the basis for the regulation of sera, vaccines, and related products, and represents the origin of biologics regulation in the United States. The second prohibited interstate commerce in misbranded and adulterated food and drugs, and provided the basis for regulation in these areas. The third dealt with sanitation in meat-packing plants. These laws were all motivated by tragic events and/or disclosures of clearly dangerous conditions and procedures in the preparation of food and drugs marketed to the U.S. population.

In 1938, the Federal Food, Drug, and Cosmetic (FDC) Act was passed. This act substantially extended the responsibilities of the executive branch with regard to the regulation of these products. Cosmetics and therapeutic devices became subject to safety requirements; drugs were required to be shown safe prior to marketing; inspections of manufacturing facilities were authorized; and a variety of standards were established for foods. Shortly after this legislation was enacted, the regulatory authority for food and drugs was moved from the Department of Agriculture to the Federal Security Agency, and the first Commissioner of Food and Drugs, Walter G. Campbell, was appointed in 1940. (In 1953, the Federal Security Agency became the Department of Health, Education, and Welfare, the predecessor of the current DHHS.)

In 1962, the FDC Act was amended to require for the first time that drugs be demonstrated effective as well as safe prior to being approved for marketing. Provisions strengthening drug safety requirements were also included. These legislative actions were motivated largely by the discovery that thalidomide, a sleeping pill marketed widely outside the United States, was responsible for an epidemic of birth defects.

More recent milestones in food and drug regulation include the transfer of the Bureau of Radiological Health to the FDA in 1971; the transfer of responsibility for the regulation of biologics from the NIH to the FDA in 1972 and the initiation of over-the-counter drug review that same year; the passage of medical device amendments in 1976, formalizing and strengthening regulation in this growing area; the Orphan Drug Act of 1983, promoting the development of drugs needed to treat rare diseases; and the Prescription Drug User Fee Act (PDUFA) of 1992, requiring manufacturers of drugs and biologics to pay fees related to the submission of marketing applications. As a result of these acts, the FDA is authorized by Congress to monitor activity surrounding U.S.\$1 trillion worth of goods annually, approximately one-quarter of the gross national product. Each of the six centers of the FDA plays an important role in helping to accomplish this enormous task.

FOOD AND DRUG ADMINISTRATION CENTERS AND THE PRODUCT DEVELOPMENT PROCESS

Four of the FDA’s six centers—CBER, CDER, CDRH, and CVM—focus on biopharmaceutical/biomedical products. We will focus most of our discussions on these four centers. The primary tasks of these centers relate to the oversight of product development and the evaluation of licensing applications for new products (or new uses of old products). Regulatory requirements for drugs and biologics can be found in the Code of Federal Regulations, Title 21 (Food and Drugs), Chapter 1 (The Food and Drug Administration), Subchapter D (Parts 300–499); requirements specific to veterinary products in Subchapter E (Parts 500–599); requirements specific to biologics in Subchapter F (Parts 600–699); and requirements for medical devices and radiological health in Subchapters H–J (Parts 800–1050).

For drugs and biologics intended for human use, the regulatory cycle begins when the product developer, or sponsor, intends to begin the first studies in humans. At that time, an investigational new drug (IND) application is submitted to the agency. Sufficient preclinical data must be provided in this application to support the safety and the rationale for the use of the product. For medical devices,

such applications are required only for specific classes of devices that pose “substantial risk.” In these cases, an investigational device exemption (IDE) application will be submitted. Reviewers for the FDA (representing a variety of disciplines depending on the product) will consider the application and will determine whether clinical investigations may proceed.

Plans for each clinical study to be carried out must be submitted to the agency prior to initiation if the studies are to be carried out in the United States. The review of these studies by the FDA serves several functions. First, this review provides an additional check on safety assurance that the study is unlikely to result in harm to participants. Second, the FDA reviewers will assess whether the study design is likely to achieve its goals, and they may make suggestions to the sponsor regarding the approach taken. An interaction between the sponsor and the FDA at the early stages of drug development can be extremely helpful in ensuring that the development strategy laid out by the sponsor will ultimately provide the persuasive data regarding safety and efficacy that will be necessary to gain marketing approval.

The culmination of the sponsor’s evaluation of the product is the submission of a dossier to the appropriate agency: for pharmaceuticals, a new drug application (NDA) to the CDER; for biologics, a biologics licensing application (BLA) to the CBER; and for medical devices, a premarket assessment (PMA) to the CDRH. This comprehensive package must summarize the efficacy and the safety of the investigational drug, biologic, or device as demonstrated by clinical and other studies. It must also contain adequate evidence that the product will have the effect that the sponsor claims under the conditions of use (505(d) FDA Act). The necessary components of a submission package have been clearly defined by the appropriate center of the FDA and can be found easily on the Internet (<http://www.fda.gov>). In the case of an NDA, the dossier must contain an application summary, copies of study protocol(s), study reports, integrated summaries of efficacy and safety, and proposed product labeling (package insert).

In addition to reviewing data from studies evaluating product, the FDA engages in a wide variety of oversight activities. Product manufacturing processes are held to established standards, and manufacturing facilities are inspected by the FDA staff at regular intervals to ensure compliance with the regulations. The FDA inspectors also visit clinical sites where studies are carried out to document that correct and appropriate data were recorded, that all patients treated with investigational product were accounted for in study reports, and that study procedures were followed according to the study protocol. The records of Institutional Review Boards (IRBs) are also subject to scrutiny by the FDA inspectors.

The FDA’s responsibility for ensuring product safety does not end with the decision that a product may be marketed. Manufacturers are required to report adverse

experiences associated with their products to the FDA within timelines dependent on the type of experience. These reports, together with others received directly from health care providers and consumers, are reviewed by the FDA to determine if changes are needed in the way the product is labeled, marketed, or prescribed.

STATISTICS AT THE FOOD AND DRUG ADMINISTRATION

Each of the FDA’s six centers has its own statistical unit. In 1998, the number of statisticians employed by the FDA was approximately 150. FDA statisticians participate in all aspects of regulatory review, assessing laboratory and pre-clinical data as well as data from pharmacokinetic studies, early clinical assessments, and large-scale clinical trials. They are also involved in setting and evaluating standards for testing and quality control; assessing data from post-marketing safety surveillance programs; collaborating with other FDA scientists on research projects; evaluating newly proposed statistical methods potentially applicable to regulatory settings; conducting methodological research; providing training to other scientific staff; and contributing to policy development.

The CDER has the largest cadre of statisticians, divided among three divisions, and a staff devoted to special projects. Each of the three divisions includes about 20–30 statisticians and works with a particular subset of medical review divisions. For example, the Division of Biometrics I evaluates drugs for cancer, heart, kidney, and neurological/mental disorders. All other centers have a single group of statisticians, ranging in approximate size from 5 to 20. Most FDA statisticians have doctoral degrees in statistics or biostatistics.

Probably the largest fraction of statistical effort at the FDA goes into the review of licensing applications for new products. The data from studies that the sponsor believes support the efficacy and the safety of the product are generally provided in electronic format, facilitating the FDA statistical analysis. The FDA statistical reviewers will assess the analyses presented by the sponsor and may perform supplementary analyses to assist in interpreting the data presented. Some FDA statisticians attend the advisory committee meetings wherein the application is discussed and may make a presentation in cases where statistical issues need to be highlighted. The statistical assessment of the data in the application is key to the decision to approve, or not to approve, a product for marketing.

A major ongoing challenge for FDA statisticians is the evaluation of the applicability of new statistical approaches to the regulatory setting. For example, there has been increased interest in applying Bayesian methodology to clinical trials of investigational products.^[1] Statisticians at the CDRH are actively evaluating the incorporation of Bayesian methodology in the clinical development process.

Because so many new devices differ in only minimal ways from earlier versions, the formal inclusion of information on the effectiveness and the safety of these earlier versions in the evaluation of new devices is appealing. As reported by the February 1998 International Medical Device Regulatory Monitor, "The FDA is preparing to issue a guidance on an advanced statistical methodology, known as the Bayesian model, that incorporates historical information into medical device clinical trial data."^[2] For a discussion of the use of Bayesian methodology in medical device development, see Berry.^[3]

FOOD AND DRUG ADMINISTRATION RELATIONSHIP TO SPONSORS

The relationship formed between the FDA and a sponsor is extremely important. Each drug, device, or biologic that a sponsor decides to research on and submit for regulatory approval represents an enormous and risky investment. Only one in approximately 10,000 compounds tested ever makes it to the market. Additionally, of those that do eventually make it to market, the cost of testing and satisfying the regulators worldwide has been estimated as U.S.\$528–792 million by the Association of British Pharmaceutical Industry (ABPI). Due to the costly nature of the registration process, the importance of good communication between the sponsor and the FDA cannot be overemphasized.

Each center of the FDA has an office dedicated to communication with sponsors and other interested parties. These offices work to ensure that all of the FDA's customers (including representatives of the pharmaceutical industry, health care professionals, government officials in other agencies, the media, and consumers) have easy and open access to information and are fully informed about the drug regulation process.

The FDA encourages communication with the sponsor throughout the review process and specifically advocates meetings prior to the development of an IND application and immediately preceding the submission of a marketing application. In planning a meeting with the FDA, the sponsor should take great care in designing the agenda. As noted by Waymack and Rutan,^[4] sponsors should carefully consider the attendees and the content of this meeting to ensure that the relevant issues can be fully and efficiently addressed.

One important component of the review process is the presentation to one of the FDA's advisory committees by the sponsor and the FDA review team of their respective assessments of the data contained in a marketing application. These committees consist of a panel of experts—external to the FDA and independent of the sponsor—that generally includes physicians, statisticians, other scientists and health professionals, and a lay consumer representative. The committees are governed by the Federal Advisory Committee Act of 1972 and later amendments.

The primary purposes of FDA advisory committees are to review available data (efficacy and safety) for medical products under investigation for human use and to address issues as requested by the FDA to assist in labeling decisions. Advisory committees may also be asked to comment on methodological issues germane to many applications. The FDA is not required to follow the recommendations of advisory committees but does act in accordance with their recommendations in most instances. While the size of the committee can range between 10 and 15 members, the panel can be supplemented with additional experts on an ad hoc basis when necessary for particular applications. A thorough discussion of the FDA's use of advisory committees can be found in an Institute of Medicine report that was issued in 1992^[5] and that formed the basis for many recent changes in operating procedures. For a practical article related to FDA advisory committees, see, for example, Farley.^[6]

FOOD AND DRUG ADMINISTRATION GUIDANCE DOCUMENTS

A list of guidelines that have been prepared by the FDA to aid sponsors in their pursuit of regulatory product approval is maintained by each FDA center. It is important to note that guidance documents differ from regulations, in that sponsors are not required to abide by practices described in guidance documents; rather, these documents represent what the FDA considers acceptable approaches to regulated research, although there may be other approaches that are also acceptable. While guidance is provided by the FDA on many aspects of design and analysis, the responsibility for adequate studies and credible analyses ultimately lies with the sponsor. A list of all guidelines that apply to the FDA's regulations across all centers, as well as the corresponding documents, can be found at the FDA's website (<http://www.fda.gov/opacom/morechoices/industry/guidedc.htm>).

An important ongoing initiative of the FDA is participation in the International Conference on Harmonization (ICH). The ICH comprises a joint effort of regulatory authorities and the pharmaceutical industry in the United States, Europe, and Japan to standardize regulatory requirements and to establish standards for pharmaceutical research to the extent possible among these three regions, thereby reducing inefficiencies and ensuring a consistently high quality of research for manufacturers in an increasingly global industry. The ICH has developed documents in the areas of quality, safety, and efficacy, and for some crosscutting topics as well. A description of the ICH, a listing and brief description of all documents issues, and access to the full documents themselves can be found at the ICH website (<http://www.ifpma.org.ich1.html>).

An ICH guideline entitled "Statistical Principles for Clinical Trials" has recently been issued by the FDA as

a guidance document (<http://www.fda.gov/ohrms/dockets/98fr/091698c.txt>). This document discusses approaches to trial design and analysis in terms of the prevention of bias and the preservation of the desired error probabilities. This document should help ensure that adequate attention is given to statistical considerations for studies of new pharmaceutical products performed in the three ICH regions, and should facilitate the acceptability of registration data collected for marketing authorization in one region by regulatory authorities in the others.

COMMON PROBLEMS AND CURRENT CONTROVERSIES

As methods for clinical research become more sophisticated, the approaches to evaluating investigational medical products also evolve. In many cases, FDA regulations and guidelines may be updated to account for new information. For example, guidance documents were updated in the late 1980s to account for methods of interim analysis that were becoming widely used in trials with mortality or major morbidity endpoints. In addition, patient groups in recent years have raised concerns about FDA regulations being so focused on the protection of study subjects that many individuals were being denied access to clinical trials. These policies had the effect (perhaps inappropriately) of restricting access to investigational therapy of some patient groups, as well as reducing the generalizability of the data generated. As a result, guidance documents have been made available to stress the importance that all relevant subgroup populations should be included in clinical trials.

Despite the ready availability of FDA regulations and guidelines, as described earlier, and the continual reassessment of optimal research approaches, certain problems regularly arise. These issues include the size of studies, the appropriate control group, the appropriate population(s) to study, and the primary and secondary study endpoints that will define the product efficacy. It is important to demonstrate efficacy and safety in a way that not only meets the requirements of regulatory agencies, but also documents and motivates use from both a clinical and a commercial perspective.

Study Size

Study size is determined by the desired error probabilities and the estimated effects of the investigational and control treatments. Companies wish to perform the smallest possible studies that will still be adequate to demonstrate efficacy and safety. In some cases, FDA reviewers believe that the company is overly optimistic about the expected effects of the new treatment and suggest that a study be enlarged to be able to detect more modest, but still clinically important, effects. In some instances, the study size proposed may be adequate to assess the primary endpoint

but not important secondary endpoints or specific safety concerns.

Control Group

There are a number of aspects to the selection of a control group: chronology (historical vs. concurrent controls); treatment assignment method (randomized vs. systematic); type of control treatment (active vs. inactive); and approach to blinding (double-blind, single-blind, open label). The randomized, double-blind, placebo-controlled trial is generally considered the optimal approach but is not feasible in all instances. For example, active controls rather than placebo controls would be used when available active treatment is known to prevent or delay death or major morbidity. Random allocation of patients between treatment and control is considered essential, in most instances, to a reliable interpretation of observed treatment effects. However, historical controls have been accepted as a basis for approval in some instances when the target patient population is extremely small and/or the effect of the new product is so dramatic as to make selection bias an unlikely explanation for the outcome.

Study Population

The definition of the study population is extremely important. Clearly, one wishes to study a new treatment in a population in which it is most likely to prove effective. Thus individuals whose disease is so minimal that improvements would be difficult to document and individuals whose disease is so advanced that no treatment is likely to be effective are generally not considered for studies of new products. On the other hand, it is important to study the treatment in the population for which it is likely to be prescribed, should the study be positive and should the product be marketed. Attention is given at the design stage to ensure the inclusion of the elderly, women, and children in studies of treatments likely to be used in these populations.

Primary and Secondary Endpoints

The *primary* endpoint for the trial must provide an adequate basis for assessing the clinical value of the treatment. Most of the discussions between the FDA and the sponsors center around the choice of clinical trial endpoints. Endpoints may be measured as continuous, binary, or multinomial variables, as time to an event of interest, as counts of events over a specified time interval, and as the slope of a regression line, just to give a few examples. In some cases, a *composite* endpoint—counting any of two or more outcomes as a primary endpoint—may be used. Such endpoints may be particularly relevant when treating conditions that have multiple manifestations, any of which might be improved by an effective treatment. The choice of endpoint will depend on the particular circumstances of

the trial and must be clearly specified in the study protocol prior to initiating the study.

Secondary endpoints are those that are important indicators of disease status and thus may provide a supportive evidence of treatment efficacy or safety. The number of secondary endpoints specified should be limited to those that are truly important to patients, and to physicians managing patients with the disease in question and likely to reflect the effects of the treatment being evaluated. Secondary endpoints generally cannot provide the basis for marketing approval in the absence of effects on the primary endpoint (see Fisher^[7] and Moye^[8] for recent extensive discussion of this issue) but can provide useful supportive data as well as further understanding of the product's mechanisms of activity.

In trials of therapies that are potentially lifesaving or have other potentially major benefits, "surrogate" endpoints—laboratory or early clinical measures that are believed to be predictive of the clinical outcome of interest—have been accepted as the basis for product approvals, with the condition that adequate studies documenting effects on the primary clinical outcome are ongoing. Because rapid approval based on surrogate endpoints implies shorter-term studies, there is a risk that longer-term safety issues might not be identified in such studies and that surrogates might not accurately predict the true risk-benefit ratio of a product.^[9,10] For this reason, the action based on surrogate endpoints is limited to settings of serious disease where agents with improved efficacy are urgently needed.

Many other topics that are debated on frequently in regulatory meetings include washout periods in crossover designs, the need for and/or adequacy of blinding, the treatment of dropouts and noncompliers in study analyses, the need for statistical adjustment for multiple comparisons, procedures for carrying out interim analyses, a definition of an equivalence margin in active control trials, and the necessary extent of follow-up for safety and efficacy assessments. Some of these issues are discussed by Lynch and Lachenbruch^[11] in the context of trials for biologics, but most of the discussion is relevant to clinical trials more generally. An excellent source of insight on current clinical trial controversies can be seen in Senn.^[12]

CHALLENGES FOR THE FUTURE

In a time of rapid pharmaceutical development and the opening of innovative research made possible by the explosion in biotechnology, the FDA is facing a number of difficult but exciting challenges. Perhaps the most obvious of these is the need to review an increasing number of new products rapidly so that new products that meet standards of safety and effectiveness can be made available to the public as quickly as possible. The PDUFA of 1992, which has been extended through September 2002, commits the FDA to faster review times for most new drugs and biologics applications. It was anticipated that this act would

enable the new product application review to be cut from 15.5 to 10 months. As shown in a progress report to Congress in 1998, the FDA has been successful in hiring and training new reviewers and is ahead of schedule in meeting the escalating PDUFA goals.

Other challenges relate to the application of new biological knowledge to the development of new products. Gene therapy is in its infancy, as are therapies involving the manipulation of a patient's own cells and then replacing them. Both of these approaches are showing the potential for improving clinical status in disease settings with currently little or no available satisfactory treatment. Gene therapy is one of a number of promising approaches for which theoretical safety concerns will need to be carefully studied. Other products, such as thalidomide (now approved for treatment of leprosy and AIDS) and xenotransplants (transplants of animal tissues to humans; not yet approved but under study), raise even stronger safety concerns. The task of balancing the risks of dramatically new treatment approaches carrying major risks with the potential benefits of such treatments for extremely ill patients will be confronted more frequently in the coming years.

USP Tests

John R. Murphy

Eli Lilly and Company, Indianapolis, Indiana, U.S.A.

Abstract

This brief entry provides an overview of United States Pharmacopeia tests which are methods and procedures by which the acceptability of drug substances and drug products are determined and adjudicated.

INTRODUCTION

United States Pharmacopeia (USP) tests are methods and procedures by which the acceptability of drug substances and drug products are determined and adjudicated. In the United States, the standards published in the United States Pharmacopeia and the National Formulary (USP/NF) are official and binding by law under the Food, Drug, and Cosmetic Act, and they apply at any time in the life of a drug, from production to consumption.^[1] Some tests for drug substances or drug products provided in the USP, such as assays for identity, strength, and purity, are specific to the particular drug, and these tests and procedures are described in detail for each drug in a section of the USP called “Official Monographs.” Other tests, such as uniformity of dosage units, dissolution, disintegration, deliverable volume, and particulate matter, are common to many drugs and are provided in what are called “General Chapters.”

HISTORY

The USP is a publication of the USP Convention, which is an organization of both individuals and institutions having interest and expertise in drug standards. The first meeting of the USP Convention was in 1820; the first USP was published later that year, consisting of 272 pages and listing 217 drugs worthy of recognition, for guiding pharmacists and physicians in making simple mixtures and preparations. In its present-day form, the USP contains standards of identity, quality, strength, and purity for over 3000 drugs and substances in “Official Monographs.” In addition to the compilations in the “Official Monographs,” the sections called “General Tests and Assays” and “General Information” cover such subjects as analytical methods, biological assays, how to clean glassware, the laws and regulations governing drug manufacturing and distribution, stability issues, validation of compendial methods, sterility, etc. Similar compendia, such as the *British Pharmacopeia*, the *European Pharmacopeia*, and the *Japanese*

Pharmacopeia, apply to drug products marketed in those areas of the world.

A great deal of confusion exists concerning the application of USP tests. For example, it is widely believed that manufacturers must perform the USP tests to release products to the market and that they must perform them exactly as given in the USP. Neither statement is true, as the USP clearly states in its “Preamble.” On the other hand, as the USP tests and procedures are the standards by which drug products will be evaluated after they are released to the market, they are sometimes used as lot release criteria. This practice carries a degree of risk because there is little assurance that the product will pass future USP tests, given only that it has passed the USP test once at release. As the cost associated with the failure of the product in the marketplace to meet compendial requirements is great, manufacturers often adopt “in-house” product release procedures that differ from the actual USP tests but that still provides assurance that the product will meet USP standards throughout its shelf life.

Many USP tests have the look and feel of statistical sampling plans, but the USP discourages this interpretation. In its “Preface,” the USP explains that the standards apply to specimens of compendial articles and that although some tests apply to specimens consisting of multiple-dosage units, they still comprise one determination of the particular attributes of the specimen. Thus, for example, although the USP Uniformity of Dosage Forms calls for up to 30 individual dosage units, the result of the test is the determination of uniformity or the lack thereof of one single specimen. The confusion of USP tests with sampling and acceptance plans also contributes to a misunderstanding about what it means when a USP test is not met. The USP position is that inferences about the quality of the batch or the process is not necessarily warranted from a single test on a single specimen. Nevertheless, a prudent manufacturer will want to be satisfied that there is a high probability that any specimen in commercial distribution has a high probability of meeting USP requirements and will gain assurance that this is the case through internal sampling

and acceptance procedures. Although the USP tests should not be interpreted as sampling and acceptance plans, it is still possible to evaluate their hypothetical performance by means of operating characteristic (OC) curves, which display the probability that a particular test will be passed as a function of one or more measures of conformance.

CONCLUSION

In summary, USP tests are the official and statutory means by which identity, quality, strength, and purity are judged for drugs marketed in the United States. The various tests and procedures for performing them are given in the USP/NF in “Official Monographs” and in “General Chapters.” Any specimen of any article in commercial distribution

must comply with USP standards at any time throughout shelf life, and manufacturers are expected to perform the necessary sampling and testing to have a high level of assurance that pharmaceutical products conform to USP standards.

Abstract

This entry introduces typical studies conducted in the validation process of quantitative and qualitative assays and explains for each study its purpose, statistical model, parameters, and the hypothesis being tested.

Keywords: Assay validation; Quantitative; Qualitative assays.

INTRODUCTION

After an assay has been developed in a laboratory and before it can be used in clinical application (such as the diagnosis of a patient's disease), a rigid clinical validation is carried out to demonstrate that the procedure is fit for use. The clinical validation process can be divided into two categories: one for quantitative assay; the other for qualitative one. (Whether an assay is quantitative or qualitative is decided during the developing stage of an assay.) Within each category, a full, partial, or cross validation might be needed.^[1]

This entry will introduce typical studies conducted in the validation process of quantitative and qualitative assays. The key difference and similarity between quantitative and qualitative assays are discussed in the section "The Key Difference and Similarity Between Quantitative and Qualitative Assays." Typical studies conducted to validate quantitative and qualitative assays are addressed in sections "Evaluation of Quantitative Assays" and "Evaluation of Qualitative Assays." Some concluding remarks are given in the last section.

This entry is written based on clinical and laboratory standards established by the Clinical and Laboratory Standards Institute (CLSI), which was renamed in 2005 (it was originally called the National Committee on Clinical Laboratory Standards (NCCLS). Occasionally, the other standards-setting body is also mentioned in this entry: the U.S. Pharmacopeia (USP). USP is an official public standards-setting authority for all prescription and over-the-counter medicines and other health-care products manufactured or sold in the United States. USP also sets widely recognized standards for food ingredients and dietary supplements and for the quality, purity, strength, and consistency of these products.

THE KEY DIFFERENCE AND SIMILARITY BETWEEN QUANTITATIVE AND QUALITATIVE ASSAYS

The key difference and similarity between quantitative and qualitative assays are discussed below.

An obvious key difference between quantitative and qualitative assays can be seen from "quantitative" and "qualitative." A quantitative assay usually measures the concentration of an analyte. The reported concentration level is distributed within a continuous range of values. A qualitative assay, on the other hand, produces dichotomous results only, such as "positive/negative," "abnormal/normal" statements. In practice, both quantitative and qualitative assays have broad applications. For example, Pharmacokinetics analysis, based on values measured by quantitative assays, gives indications of how much drug is in the blood stream and how long it lasts; hence, reasonable treatment regimens and frequency can be determined. An example for the use of qualitative assays is to diagnose if a patient is HIV-positive or -negative.

A key similarity between quantitative and qualitative assays is that usually a monotone increasing relationship exists between the response and concentration level, where the response of a qualitative assay is its raw response (before it is categorized into "positive/negative"). The monotone relationship of a quantitative assay between the response and concentration level can be seen through linearity study (See section "Accuracy"). The monotone relationship of a qualitative assay between the raw response and concentration level can be seen from the precision study of a qualitative assay. The monotone relationship of a qualitative assay had not been incorporated into clinical studies, as pointed out in.^[2]

The key difference constitutes the different validation studies of quantitative and qualitative assays; and the key similarity constitutes the similar study, as discussed in the following sections.

EVALUATION OF QUANTITATIVE ASSAYS

Introduction

The objective of validation of a quantitative assay procedure is to demonstrate that the assay is suitable for its intended purpose.^[3] Typical performance characteristics for consideration during the validation of the analytical procedures are accuracy, precision, selectivity (specificity), limit of detection (LOD), limit of quantitation (LOQ), linearity, and range. Which characteristic needs to be validated for a particular assay is described in.³ The validation of accuracy, precision, selectivity (section “Matrix Effects”), linearity and range, and LOD and LOQ are included in the following subsections.

Accuracy

The accuracy (trueness) of an analytical procedure expresses the closeness of agreement between the “true” value and the value found, where the “true” value is accepted either as a conventional true value or an accepted reference value.^[3] Using the concentration of an analyte in a sample as an example, the true concentration is the targeted true value. This true concentration can be “known” or unknown as explained below.

A sample prepared by adding a certain amount of the analyte to a tube of excipient is assumed to have a “known” concentration. The “known” concentration of the sample is calculated using appropriate (theoretical) methods, though the calculated concentration might be different from the real concentration due to possible interaction between the added analyte and excipient. In this case, a validation called recovery study is usually conducted.

The other case is that when patient samples are used to validate the accuracy of an assay. In this case, the true concentration is unknown. The validation of the accuracy of an assay is usually conducted by comparing the proposed assay’s results to the results of an established assay. This validation is called “method comparison.”

It should be pointed out that the recovery study and method comparison cannot be viewed as a replacement for each other. The recovery study is conducted in the development stage of an assay and confirmed at validation stage. On the other hand, even an assay is validated through a recovery study; it might not be ready for clinical applications, since clinical normal range, etc., might not have been established yet.

Hence, the validation of accuracy is divided into two parts according to the true value is known (a conventional

true value exists) or unknown (a conventional true value does not exist but an accepted reference value exists). The validation for these two cases will be discussed below, respectively.

Recovery Study

As discussed above, the accuracy of an assay method is usually assessed using samples prepared by adding known amounts of ingredient to excipient in a recovery study. In this case, the concentrations of the samples are assumed fixed. However, the reported concentrations by the proposed assay are random variables. The validation can be based on the percent recovery, the absolute bias, and the percent bias.^[4] An alternative approach for the assessment of accuracy is linear regression analysis, as discussed further below.

Let y be the result by the proposed assay when measuring a sample at concentration x and y_{ij} be the result by the proposed assay at x_i at the j th repeated measurement, $i = 1, \dots, n, j = 1, \dots, k$. The first step is to assess if a linear relationship between y and x exists, using the statistical methods in section “Linearity and Range.” Once the linear relationship between y and x is established, the next step is to check if, for example, the 95% confidence intervals of a and b are within their acceptable ranges, $(-0.5, 0.5)$ and $(0.9, 1.1)$, respectively, with 95% assurance, where a and b are parameters in the following model

$$y_{ij} = a + bx_i + \varepsilon_{ij}, \varepsilon_{ij} \sim N(0, \sigma^2), i = 1, \dots, n; \quad j = 1, \dots, k.$$

If these confidence intervals are within their acceptable ranges, then the assay is accepted as accurate; otherwise, it is rejected. When the measurement errors are not constant across all concentration levels, the weighted regression approach might be used.^[5]

Method Comparison

The purpose of method comparison is primarily to determine whether the method being validated is a suitable replacement for a current method. During a quantitative assay validation process, a typical situation is that other existing assays are available in the market. These existing assays are perhaps more expensive, less accurate, harder to operate, slower in speed, etc. The new assay being validated is expected to overcome some or all of these deficiencies while still maintaining values similar to the existing ones for clinical diagnoses. The similarity of values makes a full scale of clinical establishment of normal range, etc., unnecessary. Therefore, a typical design is to select one established assay as a reference, and compare the new assay to this reference assay. If the results reported by both assays are comparable, then the new assay is acceptable. The following part of section reviews the model setup, parameters to be validated, and statistical methods for method comparison.

To determine whether the new assay being validated (y) is a suitable replacement of the selected reference assay (x) or if the two methods yield equivalent results, the conditional means of both methods are usually compared. Suppose that z is an analyte concentration level of a specimen (a tube of body fluid, such as blood or urinary sample). This concentration z varies from person to person. Hence, z is a random variable. In addition, the true concentration z is usually unknown and might be unobservable. Suppose that x and y are measurements of the same specimen of true concentration z using the reference and the new methods, respectively. Therefore, a general model is

$$\begin{cases} x|z = E(x|z) + \varepsilon_{x|z}, E(\varepsilon_{x|z}) = 0, \\ y|z = E(y|z) + \varepsilon_{y|z}, E(\varepsilon_{y|z}) = 0, \end{cases}$$

where $\varepsilon_{x|z}$ is the measurement error for a given z , $E(x|z)$ is the conditional expectation for a given z , etc. As commonly seen from the precision study (section “Precision”), $Var(\varepsilon_{x|z})$ and $Var(\varepsilon_{y|z})$ are approximately proportional to z^2 . The task of method comparison is usually to show that $E(x|z)$ and $E(y|z)$ are close enough to ascertain the “agreement” of two assays. The meaning of “ $E(x|z)$ and $E(y|z)$ are close enough” will be explored further below.

Traditionally, “ $E(x|z)$ and $E(y|z)$ are close enough” is evaluated under linear assumption; that is,

$$E(y|z) = a + b, E(x|z),$$

where a and b are unknown constants. If $a = 0$ and $b = 1$, then $E(x|z) = E(y|z)$ for all z . This certainly means that $E(x|z)$ and $E(y|z)$ are close enough. Hence, the validation is to check if a is close to 0 and b is close to 1. Traditionally, the hypotheses are set up as: $H_0 : a = 0$ and $b = 1$ versus $H_1 : a \neq 0$ or $b \neq 1$.

Three classical methods to test H_0 are: classical linear regression, Deming’s regression,^[6] and Passing-Bablok method.^[7] (A complete review of these methods can be found in.^[8]) A brief description of classical regression only is given here. Classical regression assumes:

$$y = a + bx + \varepsilon, \varepsilon \sim N(0, \sigma^2)$$

where σ^2 is an unknown positive parameter. The check of linearity between y and x is done through visual inspection of a scatter plot (Fig. 1) and a bias plot (Fig. 2). The rest of the validation process follows classical linear regression procedures.

There are a few serious drawbacks of classical linear regression. The regression assumes: (i) there is no measurement error in x , the reference method; (ii) the measurement error of the assay being validated is not related to the concentration level (in other words, the measurement error is a constant); and (iii) a linear relationship between y and x . All of these assumptions might be invalid. The

Fig. 1 Scatter plot of Y vs. X . The data were from a real clinical trial, with 1258 specimens

Fig. 2 Bias plot of data of Fig. 1

assumption (iii) is essential to all regression-based methods. In practice, this assumption is often violated (see Fig. 1). When repeated measures of each specimen by each assay are available, Zhong and Shao⁹ recently proposed a few new methods, which require few assumptions. As a result, all three assumptions imposed by linear regression are not needed anymore. These methods are based on a different measure of the agreement between two assays,

$$\delta = E \left\{ \left[E(x - y | z) \right]^2 / \left[Var(x - y | z) \right] \right\}$$

δ has several nice properties. For example, $\delta = 0$ when $E(x|z) = E(y|z)$. Another example, a larger δ usually indicates greater conditional mean differences (i.e., if δ is large, $E(x|z) - E(y|z)$ is greater). The hypotheses are $H_0: \delta \geq \delta_0$ vs. $H_0: \delta \geq \delta_0$, for pre-selected δ_0 . The detailed testing methods can be found in.^[9]

Another measure of the agreement between two assays is

$$\delta_{\downarrow} 1 = E[E(x - y | z)]^2 / (E[V(x - y | z)])$$

Note that generally, $\delta_1 > \delta$. The detailed testing methods based on δ_1 can be found in Ref. [28].

Other methods for evaluating agreement of two assays are related to the concordant correlation coefficient.^[10] A serious drawback of these methods is that the reference method (x) is assumed to be a gold standard. This assumption is impractical.

Precision

The precision of an assay expresses the closeness of agreement (degree of scatter) between a series of measurements obtained from multiple sampling of the same homogenous sample under the prescribed conditions.^[3] Precision may be considered at three levels: repeatability, intermediate precision, and reproducibility. Repeatability (intra-assay precision) expresses the precision under the same operating conditions over a short interval of time. Intermediate precision expresses within-laboratories variation: different days, different analysts, different equipment, etc. Reproducibility expresses the precision between laboratories. The intermediate precision and reproducibility are also called ruggedness in the USP/NF.^[11]

Therefore, the design of validation of precision varies according to the intended use of an assay. The intended use of an assay also decides how many factors should be included in the validation. For example, if all measurements of an assay is performed by a central laboratory using only one instrument and one reagent lot, then laboratory, instrument, and reagent lot should not be included as factors in the validation. On the other hand, if more than one laboratory, reagent lot, and instrument will be used, then these factors should be included in the validation study.

A commonly used parameter to describe precision is the total coefficient of variation (CV), which is defined as the total standard deviation divided by the grand mean, in which the total variance is the sum of all variance components (factors) being considered, such as instrument, reagent lot, day and run; and the grand mean is the average of all results. The total CV, or the total %CV, instead of the total standard deviation, is used as the precision parameter since the total standard deviation changes with the concentration level of the sample (hence the grand mean). The commonly seen industrial standards of precision in %CV for assays related to hematology are below 15%. This requirement should be met within a clinically meaningful

range. A few concentration levels are usually chosen within the clinically meaningful range and the validation is then to focus on each concentration level.

To simplify our discussion, we assume that these concentration levels have been chosen and only two factors (day and run) are included in the validation. The study designs and statistical inferences in this particular situation will be discussed in the following subsections.

Study Designs and Statistical Inferences

A design of two factors (day and run) to verify the precision of an assay needs to specify how many replicates are required within a run, how many runs are required within a day, and how many days are required for the study. There are a few NCCLS guidelines which provide a few designs with different numbers of days, runs and replicates.^[12,13] However, there is no statistical justification regarding when these designs should be used and which one is optimal. A commonly used design is to run an assay in 20 days, with two runs within a day and 2 replicates within a run. A general statistical model for these designs follows.

A model for a design which operates within at least two days, with at least two replicates within each run, and with at least two runs within each day is

$$y_{ijk} = \mu + d_i + r_{j(i)} + \varepsilon_{k(ij)},$$

where y_{ijk} is the result reported by the assay, d_i is the random factor representing between-day variations, $r_{j(i)}$ is the random factor for between-run variations nested in d_i , and $\varepsilon_{k(ij)}$ is the random factor for within-run variations nested in $r_{j(i)}$; $d_i \sim N(0, \sigma_d^2)$, $r_{j(i)} \sim N(0, \sigma_r^2)$, $\varepsilon_{k(ij)} \sim N(0, \sigma_\varepsilon^2)$, d_i , $r_{j(i)}$, and $\varepsilon_{k(ij)}$ are mutually independent; μ , σ_d , σ_r , and σ_ε are unknown constants; $i = 1, \dots, D$, $j = 1, \dots, R$, $k = 1, \dots, N$; and D is the number of days, R is the number of runs, and N is the number of replicates. The total variance is defined as

$$\sigma_{total}^2 = \sigma_\varepsilon^2 + \sigma_r^2 + \sigma_d^2$$

The total CV is defined as σ_{total}/μ . In this model, the unbiased point estimate of each variance component and the total variance, and confidence intervals of σ_{total} and σ_{total}/μ are calculated as follows.

where $\bar{y}_{i..} = \frac{1}{RN} \sum_{j=1}^R \sum_{k=1}^N y_{ijk}$, $\bar{y}_{ij.} = \frac{1}{N} \sum_{k=1}^N y_{ijk}$, and $\bar{y}_{...} = \frac{1}{DRN} \sum_{i=1}^D \sum_{j=1}^R \sum_{k=1}^N y_{ijk}$. Denote $MS_\varepsilon = \frac{1}{(N-1)RD} \sum_{i=1}^D \sum_{j=1}^R \sum_{k=1}^N (y_{ijk} - \bar{y}_{ij.})^2$, $MS_r = \frac{1}{(R-1)D} \sum_{i=1}^D \sum_{j=1}^R (\bar{y}_{ij.} - \bar{y}_{i..})^2$, and $MS_d = \frac{1}{D-1} \sum_{i=1}^D (\bar{y}_{i..} - \bar{y}_{...})^2$. Then, the unbiased estimates for the variance components using the method of moments are (negative estimates should be set to 0):

$$\hat{\sigma}_\varepsilon^2 = MS_\varepsilon, \hat{\sigma}_r^2 = \frac{1}{N} (MS_r - MS_\varepsilon), \hat{\sigma}_d^2 = \frac{1}{NR} (MS_d - MS_r),$$

$$\hat{\sigma}_{total}^2 = \hat{\sigma}_\varepsilon^2 + \hat{\sigma}_r^2 + \hat{\sigma}_d^2 = \frac{N-1}{N} MS_\varepsilon + \frac{R-1}{NR} MS_r + \frac{1}{NR} MS_d.$$

The sums of squares and their expectations are:

Source	DF	SS (Sum of Squares)	MS (Mean Square)	E(MS)
Day	$D - 1$	$NR \sum_{i=1}^D (\bar{y}_{i..} - \bar{y}_{...})^2$	$\frac{NR}{D-1} \sum_{i=1}^D (\bar{y}_{i..} - \bar{y}_{...})^2$	$\sigma_\varepsilon^2 + N\sigma_r^2 + NR\sigma_d^2$
Run	$(R - 1)D$	$N \sum_{i=1}^D \sum_{j=1}^R (\bar{y}_{ij.} - \bar{y}_{i..})^2$	$\frac{N}{(R-1)D} \sum_{i=1}^D \sum_{j=1}^R (\bar{y}_{ij.} - \bar{y}_{i..})^2$	$\sigma_\varepsilon^2 + N\sigma_r^2$
Rep	$(N - 1)RD$	$\sum_{i=1}^D \sum_{j=1}^R \sum_{k=1}^N (y_{ijk} - \bar{y}_{ij.})^2$	$\frac{1}{(N-1)RD} \sum_{i=1}^D \sum_{j=1}^R \sum_{k=1}^N (y_{ijk} - \bar{y}_{ij.})^2$	σ_ε^2
Total	$NRD - 1$	$\sum_{i=1}^D \sum_{j=1}^R \sum_{k=1}^N (y_{ijk} - \bar{y}_{...})^2$		

An approximately $100*(1 - \alpha)\%$ confidence interval for σ_{total} is:

$$\left(\frac{\sqrt{T} \hat{\sigma}_{total}}{\sqrt{\chi^2_{1-\frac{\alpha}{2}}(T)}}, \frac{\sqrt{T} \hat{\sigma}_{total}}{\sqrt{\chi^2_{\frac{\alpha}{2}}(T)}} \right),$$

$$T = \frac{D[(N-1)R \cdot MS_\varepsilon + (R-1)MS_{rr} + MS_{dd}]^2}{(N-1)R \cdot MS_\varepsilon^2 + (R-1)MS_{rr}^2 + \frac{D}{D-1} MS_{dd}^2},$$

where $\chi_p^2(T)$ is the p th quantile of the χ^2 -distribution with the degrees of freedom $T(p = 1 - \alpha/2$ or $\alpha/2)$.^[14] A commonly acceptable approximate $100*(1 - \alpha)\%$ confidence interval for the total CV is

$$\left(\frac{\sqrt{T} \hat{\sigma}_{total}}{\bar{y}_{...} \sqrt{\chi^2_{1-\frac{\alpha}{2}}(T)}}, \frac{\sqrt{T} \hat{\sigma}_{total}}{\bar{y}_{...} \sqrt{\chi^2_{\frac{\alpha}{2}}(T)}} \right),$$

where $\bar{y}_{...}$ is treated as a constant in constructing the confidence interval.

Matrix Effects

The results of quantitative assays, as well as qualitative assays, are affected by many factors in practice. These factors are called “matrix effects.” For instance, the result of a hematology-related assay may be affected by interfering substances, and chemical and physical properties that are different from the ideal specimen collection and measurement conditions (such as drugs, alcohol, anticoagulants, storage conditions, etc.). (When the validation is conducted to assess unequivocally the analyte in the presence of components which may be expected to be present, it is called selectivity (specificity).^[3,11]) Using a blood-related test which measures the ferritin concentration as a specific example, the question is, does a person with excessive lipids

in his/her blood stream after a fatty meal have a positive or negative impact on the result? Another example is that specimens are usually frozen and shipped to a central laboratory for testing. If the testing results are quite different from the results tested when samples are fresh, this kind of procedure is certainly not appropriate. Hence, the objective of matrix effect validation is to confirm which matrix effect has an impact on the assay's result and which does not.

As proposed by NCCLS EP-7A,^[15] a matrix effect should be evaluated at least at two medical concentrations of the analyte. We will use the ferritin concentration in blood testing where lipid is a possible interfering substance as an example. First, at each concentration, two pools of specimens of equal concentrations of ferritin are prepared. Second, two tubes of equal amounts of solvent are prepared, one without lipids, one with “excessive” lipids. The “excessive” means that once the tube of solvent with lipids is added to a pool, it simulates the “worst case” conditions when lipids are interfering with ferritin. Finally, the two tubes of solvent are added to the two pools of specimens. One pool without added lipids is called a control pool. The other is called a test pool. These two pools should have quantity enough to allow for repeated measurements, as mandated by the power requirement to declare that there is or there isn't an interfering effect.

Let $x_1, x_2, \dots, x_n$ and $y_1, y_2, \dots, y_m$ denote the results of measurements from the control pool and test pool, respectively. Assume $x_i \sim N(\mu_0, \sigma^2)$, $y_j \sim N(\mu_1, \sigma^2)$, $i = 1, \dots, n$; $j = 1, \dots, m$; and μ_0, μ_1 , and σ are unknown constants. The matrix effect analysis is to test the following statistical hypotheses

$$H_0: |\mu_1 - \mu_0| \geq \delta \quad \text{vs.} \quad H_a: |\mu_1 - \mu_0| < \delta,$$

where δ is a pre-specified clinical acceptance limit (in difference). Sometimes, the clinical acceptance limit is given by the relative difference. Then the above hypotheses can be rewritten as

$$H_0: \left| \frac{\mu_1 - \mu_0}{\mu_0} \right| \geq \delta_r \quad \text{vs.} \quad H_a: \left| \frac{\mu_1 - \mu_0}{\mu_0} \right| < \delta_r$$

accordingly. The tests of the hypotheses above are equivalent to whether the corresponding confidence intervals are within $(-\delta, \delta)$ or $(-\delta_p, \delta_p)$, respectively, where the $(1 - \alpha)$ confidence interval for $\mu_1 - \mu_0$ is

$$(\bar{y} - \bar{x}) \pm t\left(1 - \frac{\alpha}{2}, m + n - 2\right) \cdot s_p \sqrt{\frac{1}{m} + \frac{1}{n}},$$

and the approximate $(1 - \alpha)$ confidence interval for $\frac{\mu_1 - \mu_0}{\mu_0}$ is

$$\frac{\bar{y} - \bar{x}}{\bar{x}} \pm t\left(1 - \frac{\alpha}{2}, m + n - 2\right) \cdot \frac{s_p}{\bar{x}} \sqrt{\frac{1}{m} + \frac{1}{n}}$$

$$\bar{x} = \frac{\sum_{i=1}^n x_i}{n}, \bar{y} = \frac{\sum_{i=1}^m y_i}{m}, s_p = \sqrt{\frac{(n-1)s_x^2 + (m-1)s_y^2}{n+m-2}},$$

$$s_x^2 = \frac{1}{n-1} \sum_{i=1}^n (x_i - \bar{x})^2, s_y^2 = \frac{1}{m-1} \sum_{i=1}^m (y_i - \bar{y})^2,$$

and $t(1 - \frac{\alpha}{2}, m + n - 2)$ is the $(1 - \alpha/2)$ percentile of t distribution with the degrees of freedom $m + n - 2$.

Another typical design is the one that does not pool specimens. Under this design, two tubes of specimens are collected from each subject. Then a certain amount of solvent is added to each tube, one with the interfering substance, one without the interfering substance. Each tube of specimens is then tested repeatedly by the assay. The appropriate analyses for this design are the statistical methods presented in the “Method Comparison” section.

Linearity and Range

For a quantitative assay, one essential requirement is that the results reported by the assay are linear to the true concentrations in the reportable range, where the results are the final analytical results the assay reports. The reportable range is the interval for which it has been demonstrated that the assay has a suitable level of precision, accuracy, and linearity. The reason for requiring this linear relationship is based on clinical grounds. For example, assuming that a scale of weight is an “assay,” we expect that a person weighing 200 lbs. is truly twice as heavy as a person weighing 100 lbs.

Hence, the purpose of the validation is to determine the linearity of an assay. The statistical process for this validation is to examine if fitting a model with the linear relationship is adequate or if using the quadratic or some higher-order polynomials is more appropriate.

Study Designs and Statistical Analysis

NCCLS Guideline EP6-P2^[6] recommends several study designs. One of them is the high-low pool method of preparing samples at different concentrations. The details of

this method follow: (i) Choose two samples with known concentrations, one sample with high concentration and one sample with low concentration. The concentrations of the high and low samples should be close to the upper and lower limits of the reportable range, respectively. (ii) Create a few samples with different concentration levels between the high and low concentrations by pooling various proportions of the high and low concentration samples. The concentration levels of these created samples should be evenly distributed between the concentrations of the high and low samples. For instance, if we want to create three samples with concentrations evenly distributed between the high and low concentrations, we can prepare these samples using 75%L + 25%H (75% of one unit of high concentration sample and 25% of one unit of low concentration sample), 50%L + 50%H, and 25%L + 75%H respectively. The concentrations of these created samples can be calculated from the known concentrations of the high and low samples and the proportions used to create them.

Once these samples are created, a couple of measurements of each sample are usually conducted. Suppose a third-order polynomial model is postulated to validate the linearity of the assay, i.e.,

$$y_{ij} = a + bx_i + cx_i^2 + dx_i^3 + \varepsilon_{ij},$$

where x_i is the known concentration level; y_{ij} is the measurement of the sample with concentration x_i ; a, b, c and d are unknown constants; $\varepsilon_{ij} \sim N(0, \sigma^2)$; and $i = 1, 2, \dots, n, j = 1, 2, \dots, k_i$. If the relationship between y_{ij} and x_i is linear, then c and d should be 0. Therefore, the statistical validation of linearity focuses on whether c and d are 0. A confidence interval approach based on traditional linear regression is usually utilized to reach a conclusion about the linearity of the assay. For example, if the 95% confidence interval of c is within $(-\delta_c, +\delta_c)$, then c is considered to be equivalent to 0 (δ_c is a pre-specified acceptance limit).

Further Considerations

There are a few points of caution about the statistical validation procedures presented above. First, note that a constant measurement error across all concentrations is assumed. However, this assumption is usually not true as can be seen from precision studies. If the measurement errors are proportional to the concentration level, which is true for many assays, then the weighted regression approach is preferred.^[5] Second, a third-order polynomial model is assumed first, and then we establish that the second- and third-order terms are not significant. However, confirming that the second- and third-order terms are not significant does not automatically exclude the significance of even higher-order terms. One possible solution follows:

Establish the best-fit polynomial (using a model-selection approach), $p(x)$, and the linear-fit polynomial, $l(x) = a + bx$, between y and x . The search for the best-fit

polynomial $p(x)$, for example, starts with the highest possible order of the polynomial, the number of concentration levels, and uses a backward model-selection approach. Then the biases at each concentration x , defined by

$$B(x) = p(x) - l(x),$$

are calculated. If all biases are within the pre-specified medical acceptance limits, then the linearity of the assay is accepted; otherwise, it is not accepted. However, a statistically rigid testing procedure, based on $B(x)$, needs to be studied further.

Limits of Detection and Quantitation

Limit of detection (LOD) of an assay is the lowest amount of analyte in a sample which can be detected but not necessarily quantitated as an exact value. Limit of quantitation (LOQ) of an assay is the lowest amount of analyte in a sample which can be quantitatively determined with suitable precision and accuracy.^[3] Hence, LOD is a parameter which merely substantiates that analyte concentration is above or below a certain level;^[4] LOQ is a parameter of a quantitative assay for low levels of compounds in sample metrics, and is used particularly for the determination of impurities and/or degradation products. However, there are no accepted standard interpretations of these terminologies. Although each therapeutic area might have its own conventional interpretations, it is important to understand whether the estimates are useful for the intended use.

Traditionally, the LOD of an assay has been calculated from an intra-assay measure reflecting imprecision of the zero calibrator.^[17] However, this method is generally considered clinically irrelevant and usually giving an overly optimistic estimate of LOD.^[18] A more clinically relevant measure, LOQ, or functional sensitivity, is generally more preferable. One commonly used interpretation of LOQ is the lowest concentration level at which an assay achieves a CV of 20%, which represents the lowest amount of an analyte in a sample that can be quantitatively determined with suitable precision and accuracy. This is the definition used in the estimation below.

Some ways of estimating LOD and LOQ follow. (ICH Guideline, Q2B, "Validation of analytical procedures: methodology" gives some standard and simple ways of estimating LOD and LOQ.)

The estimation of LOD is sometimes connected with analytical sensitivity. Analytical sensitivity is a threshold (cutoff) such that when an assay's result of a sample is greater than the threshold, it is considered that the sample contains some positive amount of the analyte (with a high probability). In that sense, the analyte is detected in the sample. Analytical sensitivity is obviously of interest in testing for impurities, where the presence or absence of certain undesirable substance is the critical information desired from the assay.

Analytical sensitivity is usually determined as the $(1 - \alpha)$ 100 percentile of the distribution of assay results from blank samples (with zero amount of the analyte). LOD is then estimated as the concentration of the analyte in a sample at which the assay's result is greater than the analytical sensitivity with $(1 - \alpha)$ probability.

Suppose that y is the response (after calibration) at concentration x , and

$$y \sim N(x, (a + bx)^2),$$

where a and b are unknown positive constants. Then, an example of study design and estimation procedure of estimating LOD is given below ($\alpha = 0.05$):

1. Prepare a panel with 5 members such that the target concentrations of the panel members sandwiching the underline LOD and LOQ (the concentration of the i th member is denoted as x_i).
2. Assay each member 30 times, repeatedly. (Let y_{ij} be the j th repeated measurement at x_i , $j = 1, \dots, 30$; $i = 1, \dots, 5$.)
3. Calculate $SD(x_i)$, $i = 1, \dots, 5$, using formula

$$SD(x_i) = \frac{1}{29} \sum_{j=1}^{30} (y_{ij} - \bar{y}_i)^2, \text{ where } \bar{y}_i = \frac{1}{30} \sum_{j=1}^{30} y_{ij}.$$

4. Calculate linear regression estimators $\hat{a}$ and $\hat{b}$ of a and b , using $SD(x_i)$ and x_i , $i = 1, \dots, 5$.
5. Estimate LOD using the formulas

$$LOD = 3.290\hat{a}/(1 - 1.645\hat{b}), LOQ = \hat{a}/(0.2 - \hat{b}).$$

The estimates of LOD and LOQ are "snapshots" or the point estimates of the LOD and LOQ. A better way is to present 95% confidence intervals of the LOD and LOQ. This can be achieved through classical linear regression techniques.

EVALUATION OF QUALITATIVE ASSAYS

Introduction

Sensitivity and specificity are two indices commonly used to evaluate the performance of a qualitative assay. As mentioned earlier, qualitative assays usually are designed to result only in positive/negative responses. Naturally, if patients are diseased, we want to know what the positive rate is by the assay; if patients are non-diseased, we want to know what the negative rate is by the assay. These two rates (positive and negative) are called sensitivity and specificity, respectively. However, using sensitivity and specificity as the performance measures of a qualitative assay is controversial.^[19] The question is: do these two parameters vary from population to population?

The answer to this question is “yes.” This can be seen in the following example. Suppose that the concentration of the analyte a qualitative assay measures is continuous (this is a commonly seen practical situation). As discussed in the following section, qualitative assays are established first by selecting a cutoff point in a receiver operating characteristic (ROC) analysis, and then a qualitative assay’s “raw” response is dichotomized further into “positive” or “negative,” i.e., if a raw response is greater than or equal to the cutoff, then the specimen is classified as positive; otherwise, it is negative. All assays have variations in their responses to a given concentration level; hence, a population with more diseased patients whose concentration levels are around 0 will have a greater chance of being misdiagnosed as negative, even if the two populations have equal proportions of diseased patients. This point is demonstrated further in Fig. 3.

Though sensitivity and specificity have this drawback, there are no other commonly accepted substitute measures. This limitation, however, can be resolved if each assay is validated in the population for which it is intended and labeled accordingly. This is commonly required by most regulatory agencies.

Most validations of qualitative assays are centered on sensitivity and specificity. The precision study of a qualitative assay is an exception. The precision study of a qualitative assay is almost an exact copy of the precision study of a quantitative assay. Refer to section “Precision” for further details.

The ROC analysis, the method used to estimate sensitivity and specificity, and matrix validation will be presented in the following subsections, respectively.

Fig. 3 Distributions of two populations with equal proportions of diseased patients. *Note:* For example, suppose an assay is used to diagnose HIV. In this case, though Population A and Population B have equal disease-prevalence rates, Population A has more patients with HIV analyte concentration levels close to 0 than Population B. That is, more patients from Population A were infected with HIV recently. Hence, the same HIV assay will have lower sensitivity in Population A than in Population B

ROC Analysis

As discussed in the sections “The Key Difference and Similarity Between Quantitative and Qualitative Assays” and “Introduction,” typically, a qualitative assay’s raw response (before it is dichotomized into positive/negative) is distributed within a continuous range of values and the dichotomization is based on a decision threshold, or cutoff. That is, for example, if the raw response of the assay is less than the cutoff, then the assay’s final diagnostic result is negative; otherwise, the final result is positive. The patient will be diagnosed as non-diseased (negative) or diseased (positive), accordingly. Hence, the determination of the cutoff is critical to this assay.

Since assays are rarely perfect, there are always overlaps between the raw responses of non-diseased and diseased patients. Therefore, by varying the cutoff value, any sensitivity from 0 to 1 (specificity from 1 to 0) can be obtained, and each one will have a corresponding specificity.^[20] A ROC curve is a plot of sensitivity versus 1-specificity when the cutoff value varies over the complete range of the assay’s measurements.

A ROC curve is a fundamental evaluation tool in clinical medicine. It provides a global assessment of accuracy by demonstrating the trade-off between sensitivity and specificity, which captures an assay’s ability to distinguish between alternative states of health, over the complete spectrum of operating conditions. Once the curve is generated, a user can readily go on to many activities, such as assessing the value of an assay as a diagnostic tool, selecting an optimal cutoff, and performing comparisons of assays. When the consequence of a diagnosis from an assay is associated with costs, a ROC curve can be incorporated into a clinical strategy by using decision analysis. A brief history of the applications of ROC curves in the area of medicine was described in.^[21]

In a typical process of a qualitative assay’s development, a ROC curve is used to determine an optimal cutoff. This is the focus of this section.

ROC Curve and Its Application

A ROC curve can be constructed using either a parametric or nonparametric method. A parametric method is based on the assumption that the distribution of an assay’s measurements for a diseased population and a non-diseased population are known except a few parameters. Details of parametric methods can be found in.^[22] A nonparametric method is based on the true disease-states (diseased or non-diseased) and an assay’s measurements of all samples used in the validation, which is specified further below:

- Calculate sample sensitivity and specificity when the cutoff value varies over the complete range of the assay’s measurements.

- Plot the sensitivity versus 1-specificity, using sensitivity as the y-axis and 1-specificity as the x-axis, and connect the data points in ascending order of sensitivity.

A ROC curve constructed in the manner described above is an increasing-step function and connects the two points of (0, 0) and (1, 1). An assay with perfect accuracy achieves 100% sensitivity and 100% specificity at one or more cutoff points. The ROC curve of this perfect assay goes through the point (0,1). An assay that does not distinguish between truly positive and truly negative subgroups has a ROC curve as the diagonal line connecting the points of (0, 0) and (1, 1). These are two extreme cases. An assay with good clinical performance achieves both high sensitivity and specificity, which corresponds to high sensitivity (true positive rate) and low 1-specificity (false positive rate). Assays with high diagnostic accuracy (high clinical sensitivity and specificity) have a ROC curve close to the upper left corner of the square. The closer the curve is to the upper left corner, the better the accuracy of the assay.

Based on the ROC curve, an optimal cutoff value can be determined, depending on the optimization criteria. For instance, if the goal is to maximize the sum of sensitivity and specificity, the optimal cutoff value corresponds to the point on the curve which has the longest distance to the line which connects (0, 0) and (1, 1).

An obvious drawback of a standard ROC curve is that its intrinsic connection to the cutoff values has been lost. This connection can be re-established by adding an additional axis, as shown in Fig. 4. Note that the axis labeled “cutoff” in Fig. 4 is not of linear scale. Fig. 4 was produced using SAS (PROC Gplot). The optimal cutoff value is based on the maximization of the sum of sensitivity and specificity.

Fig. 4 An example of a ROC curve with cutoff values

Other Applications of the ROC Curves

There are two other important applications of the ROC curves. One is to quantify the diagnostic accuracy of an assay by a number. The most common measure is the Area Under the ROC Curve (AUC). By convention, this area is always at least 0.5. If not, the assay can be improved by simply switching the definitions of “Positive” and “Negative.” The AUC values range between 0.5 (an assay with no test value) and 1.0 (a perfect assay).

The AUC is equivalent to the Wilcoxon rank-sum statistic or Mann-Whitney nonparametric two-sample statistic, with the positive subgroup as one sample and the negative as the other (20). It represents the probability that $X > Y$ (assuming a larger value is more likely to associate with a positive), where X is the assay’s result for a randomly selected person from the positive group and Y for a randomly selected person from the negative subgroup (in case of no tie).

The other important application is to make global comparisons of multiple assays. For a visual comparison, if the ROC curve of Assay A is always above the ROC curve of Assay B, then Assay A is uniformly better than Assay B. If two ROC curves cross at some point, then one assay is better on one side than the other, and vice versa. The AUCs of assays also can be used for statistical comparisons, and this comparison can be non-parametrical or parametrical.^[22]

Sensitivity and Specificity

By definition, sensitivity and specificity are conditional probabilities. If a gold standard testing method exists and can be applied to every specimen, then clinical trial design and analysis are quite simple. As recommended by NCCLS EP12-P,^[23] only specimens identified as “diseased” by the gold standard will be used in an estimate of sensitivity, and only specimens identified as “non-diseased” by the gold standard will be used in an estimate of specificity. In either case, binomial distribution is used in design and statistical inferences. For example, the design and statistical inferences for sensitivity are based on the total number of specimens identified as “positive” by the gold standard and the distribution of the frequency of these specimens tested as “positive” by the assay being validated is used for references.

In practice, however, it is much more difficult to get accurate estimates of sensitivity and specificity. First, this gold standard never exists in practice. Several clinically proven methods are usually used together sequentially to establish this “gold” standard method by some criterion, such as “if tested positive by any of these methods, then the specimen is assumed positive by the ‘gold’ standard; otherwise, it is negative.” Other methods to establish this gold standard can be found in.²⁴ The error introduced by this “fake” gold standard is usually ignored. The same assumption will be assumed here, that is, a gold standard

is established some way, and any error introduced by using this “fake” gold standard will be ignored.

The other, more challenging, problem is that this “fake” gold standard may not be applied to all participating patients due to unacceptable expenses or for the sake of the subjects’ welfare. For example, some diseases require taking a small piece from inside a subject’s body in order to know if the subject is diseased. To do such a test on all participating subjects, even when they are perfectly normal, is certainly unethical. Hence, any design needs to decrease the frequency of using the gold standard while still obtaining estimates of sensitivity and specificity as accurately as possible.

A design and estimation method that has long been used is called “discordant resolution.” Discordant resolution uses two steps for testing. First, it employs both a customarily used assay and the new assay being validated to evaluate all subjects. Second, the gold standard is applied to selected subjects with discordant testing results by the customarily used and the new assays. The true disease states of all subjects with concordant results are estimated as the concordant results, positive or negative, accordingly. This design, together with its estimation method, has been criticized by many.^[25,27] Other methods^[26,27] have been proposed recently. The drawback of Becker’s method^[26] is discussed in.^[2] The drawback of^[27] is that the asymptotical variances of their estimators are asymptotically equivalent to the inverse of the second phase sample size. Hence, its application is limited. One method proposed by^[2] follows.

Suppose that sensitivity is the parameter being validated (specificity is similar to sensitivity). Also, suppose that y is the assay being validated; x is the customarily used assay; z is the gold standard; and the values of x , y , and z are dichotomized from x_1 , y_1 , and z_1 respectively, where x_1 and y_1 are the raw responses of assay x and y , respectively, and z_1 is the true concentration level.

The design is to borrow strength from x_1 and y_1 for the selection of specimens to be retested by z and for the estimation of the true disease state of a specimen. The rationale is that x_1 and y_1 have some quantitative characteristics such as the fact that a larger raw response will be observed when the concentration level of the analyte in a specimen is higher. Keeping that fact in mind, and suppose at 1 (the cutoff), the standard deviations of $SD(x_1)$ and $SD(y_1)$ of x_1 and y_1 are known, then with almost 100% certainty that if a specimen has both x_1 -value less than $1 - 3 * SD(x_1)$ and y_1 -value less than $1 - 3 * SD(y_1)$, then we can conclude that the specimen is negative. Hence, retesting with z needs only to be applied to specimens of x_1 -value above $1 - 3 * SD(x_1)$ or y_1 -value above $1 - 3 * SD(y_1)$. The detailed retesting schema with z and the estimation method follow:

First, test all specimens using x and y , with their x_1 -values and y_1 -values recorded. Then, test all specimens with x_1 -values above $1 - 3 * SD(x_1)$ or y_1 -values above $1 - 3 * SD(y_1)$ using gold standard z . The true disease state of a specimen is the test result of z if the specimen is tested by

z ; otherwise, it is estimated as negative (Zhong’s method). All results then are summarized into the following table:

		Zhong’s method	
		1	0
Y	1	f_{11}	f_{10}
	0	f_{01}	f_{00}

The estimation of $SE(y)$ is:

$$SE(y) = \frac{f_{11}}{f_{01} + f_{11}}.$$

The simulations in² showed that this method is quite accurate. However, the theoretical property of this method needs to be explored further.

Matrix Effects

Matrix effects validation of qualitative assays needs to deal with similar tasks as those of quantitative assays. The design of the experiments and acceptance criteria, however, are quite different. To show the commonly used validation process, the following example uses a study which determines if excessive lipids are interfering with the assay’s ability to detect HIV.

First, approximately 30 healthy volunteers are selected. Next, each volunteer’s blood is collected in two tubes. (These specimens are then tested to confirm that they are HIV negative; HIV positives are removed.) Third, HIV positive material is added to one tube of each donor’s blood. Hence, for each donor, there is one tube of HIV negative blood, one tube of HIV positive blood. Last, a certain amount of lipids is added to each negative and positive blood tube to simulate practical situations of blood samples with excessive lipids. The acceptance criteria are that all negative specimens still tested negatively, and all positive specimens still tested positively by the assay being validated.

There are several problems with the above design and validation procedures related to sensitivity. One problem is that it is hard to decide how much HIV positive material should be added to each tube with HIV negative blood. As discussed in section “Sensitivity and Specificity,” if too much HIV analyte is added, the concentration of the HIV analyte is too high, and it is unlikely to test the blood samples negatively with the added lipids. Though clinicians usually add less than 5% of HIV analyte into each blood tube to create HIV positive specimens, it is difficult to justify too much or too little HIV analyte was added. This is, indeed, an arguable point between regulatory bodies and pharmaceutical companies. Therefore, the question is, how much HIV analyte should be added to simulate practical situations where a patient is HIV positive and the patient’s

Validation of Quantitative and Qualitative Assays

Fig. 5 The distribution of responses of the assay being investigated and its quantiles (diseased specimens)

Note: $P(y_1 < a) = 0.03$, $P(y_1 < b) = 0.06$

blood sample also contain excessive lipids. Another problem is that the sample size is decided subjectively without any statistical justification. Still, another problem is the question what the rationale of the acceptance criteria of “the positives remain positive” and “the negatives remain negative”, or “no qualitative change” is?

Zhong^[2] created a new method which can solve all the above problems for evaluation related to sensitivity. The suggested acceptance criterion for sensitivity is that the sensitivity under the testing condition is not less than the design requirement of the sensitivity of the assay under standard testing conditions, i.e.

$$SE(y | a \text{ testing condition}) \geq SE_0,$$

where SE_0 is the design requirement of sensitivity. The amount of the analyte to be added to the blood collection tube, or in other words, the allowable range $[a, b]$ measured by the assay, should be assay specific and sample-size related. Under the assumption that any specimens with the raw response values above the selected b remain positive under a testing condition, then the design and validation process is illustrated as follows.

1. Calculate the total sample size, n , for the design requirement of sensitivity under standard conditions.
2. Select two positive numbers $0 < q_0 < q_1 < 1$ and estimate the corresponding quantiles of the assay under standard conditions, where $1 - q_0 > SE_0$. For example, suppose that $SE_0 = 0.95$ and two positive numbers are selected as $q_0 = 0.03$, $q_1 = 0.06$. The corresponding quantiles to 0.03 and 0.06 of the raw response of y under standard conditions are estimated as a and b , respectively. See Fig. 5.
3. Calculate the number of positive specimens needed, using $n_1 = (q_1 - q_0) * n$.
4. Create n_1 positive specimens with a raw response distribution in $[a, b]$ the same as the raw response distribution in $[a, b]$ of all specimens under standard clinical testing conditions.

5. Add lipids to these n_1 specimens.
6. Determine if the assay is acceptable. If all n_1 specimens are positive, then the testing condition is acceptable; otherwise, it is unacceptable.

The above schema, however, is not workable for evaluating specificity. The difficulty comes from creating negative specimens with raw responses close to the cutoff. Our current designs might be invalid when evaluating negative populations. This may explain why so many false positive cases have been reported.

CONCLUDING REMARKS

In this entry, we introduced typical studies conducted in the validation of quantitative and qualitative assays. The purpose of each study, the statistical model used, the parameters estimated, and hypotheses tested were explained in each subsection. However, we did not try to cover all studies conducted in the validation process.

Plenty of statistical technologies have been used in the validation process. At the same time, there are many statistical problems unsolved. Some of these unsolved problems are mentioned throughout this entry.

ACKNOWLEDGMENT

We would like to express our sincere gratitude to Ms. Kathryn Nordhaus for her assistance in preparing this manuscript.

Weibull Model: Group Sequential Design

Jianrong Wu

Department of Biostatistics, St. Jude Children's Research Hospital, Memphis, Tennessee, U.S.A.

Abstract

A multistage group sequential procedure is presented under the Weibull model by applying sequential conditional probability ratio test methodology.

Keywords: Brownian motion; Group sequential trial; Randomized clinical trial; Sample size; Time to event; Weibull distribution.

INTRODUCTION

In cancer clinical trials, time to event is often a primary end point for the study design. The primary interest is to compare the survival distributions between treatment groups. For ethical reasons, randomized phase III clinical trials are often monitored for early stopping if a sufficiently large treatment difference is observed during an interim analysis. Various group sequential monitoring methods have been developed in the past few decades; e.g., the type I error spending function approach by Lan and DeMets,^[1] the triangular test by Whitehead and Stratton,^[2] and the sequential conditional probability ratio test (SCPRT) by Xiong.^[3] Comprehensive reviews of these methods are provided by Jennison and Turnbull.^[4]

For survival data, the Weibull distribution is the most frequently used parametric model. In general, a survival trial under the Weibull model can also be designed under the proportional hazards model using the non-parametric log-rank test. However, a parametric test derived under the Weibull model has better small sample properties than the non-parametric log-rank test. The maximum sample size is often large for a phase III group sequential trial. However, the available data could be small in the early stages of interim monitoring; therefore, a group sequential design using a parametric test may perform better than the non-parametric log-rank test. Tsiatis, Boucher, and Kim^[5] derived asymptotic sequential distributions for score and Wald tests in general parametric survival models. Applying results derived by Tsiatis, Boucher, and Kim, Wu and Xiong^[6] proposed a multistage group sequential design under the Weibull model.

SEQUENTIAL TEST STATISTICS

A parametric sequential test statistic is discussed in this section to provide group sequential design for randomized

two-arm survival trials under the Weibull model. Assume that time-to-event variable T_j of a subject from the j^{th} group follows the Weibull distribution with a common shape parameter κ and a scale parameter ρ_j , where $j = 1, 2$. That is, T_j has a survival distribution function,

$$S_j(t) = e^{-(\rho_j t)^\kappa} \quad (1)$$

and a hazard function,

$$h_j(t) = \kappa \rho_j^\kappa t^{\kappa-1} \quad (2)$$

The shape parameter κ indicates the degree of acceleration ($\kappa > 1$) or deceleration ($\kappa < 1$) of the hazard over time. In a cancer trial, the median survival time is an intuitive end point for clinicians. The median survival time of the j^{th} group for the Weibull distribution can be calculated as $m_j = \rho_j^{-1} \{\log(2)\}^{1/\kappa}$. Therefore, the Weibull survival distribution can be expressed as:

$$S_j(t) = e^{-\log(2) \left(\frac{t}{m_j}\right)^\kappa}, \quad j = 1, 2 \quad (3)$$

The one-sided hypothesis of a randomized two-arm trial defined by median survival times can be expressed as:

$$H_0 : m_1 \geq m_2 \quad \text{vs.} \quad H_1 : m_1 < m_2 \quad (4)$$

For notational convenience, we convert the scale parameter ρ_j to a hazard parameter $\lambda_j = \rho_j^\kappa = \log(2)/m_j^\kappa$. Then, the above hypothesis on median survival times is equivalent to the following:

$$H_0^* : \delta \leq 1 \quad \text{vs.} \quad H_1^* : \delta > 1 \quad (5)$$

where $\delta = \lambda_2/\lambda_1 = (m_1/m_2)^\kappa$ is the hazard ratio. The survival distribution is $S_j(t) = e^{-\lambda_j t^\kappa}$ and hazard function is $h_j(t) = \kappa \lambda_j t^{\kappa-1}$ for j^{th} group, in which κ is taken as a

known constant. This indicates that the testing problem can also fit into a proportional hazard model and the log-rank test is applicable for the intended testing.

Now, suppose that during the accrual phase of the trial, n_j subjects of the j^{th} group are enrolled in the study, and let T_{ij} and C_{ij} denote, respectively, the event time and censoring time of the i^{th} subject of the j^{th} group, with both being measured from the time of study entry, Y_{ij} . We assume that the event time T_{ij} is independent of the censoring time C_{ij} and entry time Y_{ij} , and $\{(Y_{ij}, T_{ij}, C_{ij}); i = 1, \dots, n_j, j = 1, 2\}$ are independent and identically distributed within each group. When the data are examined at calendar time $t \leq \tau$, where τ is the study duration, we observe the time-to-event $X_{ij}(t) = T_{ij} \wedge C_{ij} \wedge (t - Y_{ij})^+$ and failure (or event) indicator $\Delta_{ij}(t) = I(T_{ij} \leq C_{ij} \wedge (t - Y_{ij})^+)$, where $i = 1, \dots, n_j$ and $j = 1, 2$. Based on the observed data $L(\lambda_1, \lambda_2; t) = \lambda_1^{d_1(t)} \lambda_2^{d_2(t)} e^{-\lambda_1 U_1(t) - \lambda_2 U_2(t)}$, the observed likelihood function at time t is proportional to:

$$L(\lambda_1, \lambda_2; t) = \lambda_1^{d_1(t)} \lambda_2^{d_2(t)} e^{-\lambda_1 U_1(t) - \lambda_2 U_2(t)} \quad (6)$$

where $d_j(t) = \sum_{i=1}^{n_j} \Delta_{ij}(t)$ is the total number of events observed in the j^{th} group by time t , and $U_j(t) = \sum_{i=1}^{n_j} X_{ij}(t)$ is the cumulative follow-up time by time t penalized by the Weibull shape parameter κ .^[7] The maximum likelihood estimate of $\lambda_j(t)$ can be derived as:

$$\hat{\lambda}_j(t) = d_j(t) / U_j(t) \quad (7)$$

and its variance is approximately $\hat{\lambda}_j^2(t) / d_j(t)$. Therefore, under the null hypothesis, the Wald statistic of the log-hazard ratio $\gamma = \log(\delta)$ at calendar time t is given by:

$$Z(t) = \log\{U_2(t)d_1(t)/U_1(t)d_2(t)\}(d_1^{-1}(t) + d_2^{-1}(t))^{-1/2} \quad (8)$$

and has approximately a standard normal distribution.^[6] To derive the group sequential design, let

$$U(t) = \log\{U_2(t)d_1(t)/U_1(t)d_2(t)\}(d_1^{-1}(t) + d_2^{-1}(t))^{-1} \quad (9)$$

then under the alternative, the statistic $U(t)$ is approximately normal with mean $\log(\delta)V(t)$ and variance $V(t)$ and has an independent increment structure, where $V(t) = (d_1^{-1}(t) + d_2^{-1}(t))^{-1}$. The above results can be obtained from Tsiatis, Boucher, and Kim^[5] who proved the results for general survival parametric models. Since,

$$n_1^{-1}V(t) \rightarrow D(t) = (p_1^{-1}(t) + \pi^{-1}p_2^{-1}(t))^{-1} \quad (10)$$

where $p_j(t) = P(\Delta_{ij}(t) = 1)$ and $\pi = n_2/n_1$ is the treatment allocation ratio. Thus, $B(t^*) = n_1^{1/2}U(t)/D^{1/2}(t) \sim N(\theta t^*, t^*)$ is approximately a Brownian motion with drift parameter $\theta = n_1^{1/2} \log(\delta)D^{1/2}(\tau)$ and information time $t^* = D(t)/D(\tau)$, where $D(\tau)$ is the value of $D(t)$ at $t = \tau$.

SAMPLE SIZE FOR FIXED SAMPLE TEST

The sample size for a fixed sample test is calculated for the situation at the end of the study. Based on test statistic $Z(t)$ at $t = \tau$, under the null hypothesis,

$$Z(\tau) = \log\{U_2(\tau)d_1(\tau)/U_1(\tau)d_2(\tau)\}(d_1^{-1}(\tau) + d_2^{-1}(\tau))^{-1/2} \quad (11)$$

has an approximate standard normal distribution. To calculate the power, let $p_j(\tau)$ be the probability of a subject from the j^{th} group having an event during the study. Then under the alternative $\delta = \lambda_1/\lambda_2 > 1$, $Z(\tau)$ is approximately normal distributed with mean $n_1^{1/2} \log(\delta)D^{1/2}(\tau)$ and unit variance. Therefore, given a significance level α , the power $(1 - \beta)$ of the $Z(\tau)$ test under the alternative is given by:

$$1 - \beta = \Phi\left\{n_1^{1/2} \log(\delta)(p_1^{-1}(\tau) + \pi^{-1}p_2^{-1}(\tau))^{-1/2} - z_{1-\alpha}\right\} \quad (12)$$

where $\Phi(\cdot)$ is the standard normal distribution function and $z_{1-\alpha} = \Phi^{-1}(1 - \alpha)$. Thus, based on the $Z(\tau)$ test, the sample size of the first group can be calculated as:

$$n_1 = \frac{(z_{1-\alpha} + z_{1-\beta})^2(p_1^{-1}(\tau) + \pi^{-1}p_2^{-1}(\tau))}{[\log(\delta)]^2} \quad (13)$$

where $\delta = R^\kappa$. Therefore, the total sample size for the two groups is given by:

$$n = \frac{(\pi + 1)(z_{1-\alpha} + z_{1-\beta})^2(p_1^{-1}(\tau) + \pi^{-1}p_2^{-1}(\tau))}{[\log(\delta)]^2} \quad (14)$$

To calculate the number of subjects required for the study, we need to calculate $p_j(\tau)$, the probability of a subject in the j^{th} group having an event during the study. Typically, we assume that subjects are accrued over an accrual period of length t_a with an additional follow-up period of length t_r . A subject enters the study at time u , the entry time is uniformly distributed on $[0, t_a]$, and no subject is lost to follow-up during the study. Then the probability of a subject having an event during the study under the Weibull model can be calculated by:

$$p_j(\tau) = 1 - \frac{1}{t_a} \int_{t_r}^{t_a+t_r} e^{-\log(2)\left(\frac{u}{m_j}\right)^\kappa} du \quad (15)$$

Therefore, given the design parameters $\kappa, m_1, m_2, \alpha, \beta, \pi, t_r$ and t_a , the number of subjects n required for the study can be calculated using equation 14.

When designing an actual trial with accrual time t_a , calculating the sample size is often impractical, because we may not be able to enroll the planned number of subjects within the given accrual duration. It is more practical to design the study by starting with the given accrual rate r and then calculate the required accrual time t_a . This can

be accomplished under the Weibull model assumption. We can define a root function of the accrual time t_a ,

$$\text{root}(t_a) = \text{rt}_a - \frac{(\pi + 1)(z_{1-\alpha} + z_{1-\beta})^2 (p_1^{-1}(t_a + t_f) + \pi^{-1}p_2^{-1}(t_a + t_f))}{[\log(\delta)]^2} \quad (16)$$

The accrual time t_a can now be obtained by solving the root equation $\text{root}(t_a) = 0$ numerically in R using the “uni-root” function. The total sample size required for the study is approximately $n = [\text{rt}_a]^+$, where $[x]^+$ denotes the smallest integer greater than x .

GROUP SEQUENTIAL PROCEDURE

In this section, we will apply an SCPRT procedure to the test statistic $Z(t)$. The SCPRT has two unique features: 1) the maximum sample size of the sequential test is not greater than the size of the reference fixed sample test and 2) the probability of discordance, or the probability that the conclusion of the sequential test would be reversed if the experiment was not stopped according to the stopping rule but continued to the planned end, can be controlled to an arbitrarily small level.^[8] Furthermore, the power function of the SCPRT is virtually the same as that of the fixed sample test.^[3] The SCPRT boundaries derived in this entry have analytical solutions. All these features make the SCPRT attractive and simple to use.

Let $\{B_{t^*} : 0 < t^* \leq 1\}$ be the Brownian motion $B_{t^*} \sim N(\theta t^*, t^*)$ and B_1 be the B_{t^*} at the final stage with full information $t^* = 1$. Then the joint distribution of (B_{t^*}, B_1) has a bivariate distribution with mean $\mu = (\theta t^*, \theta)$ and a variance matrix $\Sigma = (\sigma_{ij})_{2 \times 2}$ with $\sigma_{11} = \sigma_{12} = \sigma_{21} = t^*$ and $\sigma_{22} = 1$. Therefore, according to multivariate conditional distribution theory,^[9] the conditional density $f(B_{t^*} | B_1)$ is the normal density of $N(B_1 t^*, (1 - t^*) t^*)$. Let $s_0 = z_{1-\alpha}$ be the critical value of B_1 to reject the null for the fixed sample test. Then the conditional maximum likelihood ratio for the stochastic process on information time t^* is:^[3,10]

$$L(t^*, B_{t^*} | z_{1-\alpha}) = \frac{\max_{\{s > s_0\}} f(B_{t^*} | B_1 = s)}{\max_{\{s \leq s_0\}} f(B_{t^*} | B_1 = s)} \quad (17)$$

Taking the logarithm, the log-likelihood ratio can be simplified as:

$$\log\{L(t^*, B_{t^*} | z_{1-\alpha})\} = \pm \frac{(B_{t^*} - z_{1-\alpha} t^*)^2}{2(1 - t^*) t^*} \quad (18)$$

which has a positive sign if $B_{t^*} > z_{1-\alpha} t^*$ and a negative sign if $B_{t^*} < z_{1-\alpha} t^*$. This equation leads to lower and upper boundaries for $B_{t_k^*}$ as:

$$\begin{aligned} a_k &= z_{1-\alpha} t_k^* - \{2at_k^*(1 - t_k^*)\}^{1/2}; \\ b_k &= z_{1-\alpha} t_k^* + \{2at_k^*(1 - t_k^*)\}^{1/2}, \end{aligned} \quad (19)$$

for $k = 1, \dots, K$, where K is the total number of looks, and $t_1^*, t_2^*, \dots, t_K^* (= 1)$ are the information times of the interim looks and the final look. The a in Eq. 19 is the boundary coefficient, and it is crucial to choose an appropriate a for the design such that the probability of conclusion by the sequential test being reversed by the test at the planned end is small but not unnecessarily small. The larger a is, the smaller is the discordance probability, and the wider apart the upper and lower boundaries are, making it harder for the sample path to reach the boundaries and stop early and resulting in larger expected sample sizes. Thus, an appropriate a can be determined by choosing an appropriate discordance probability.^[3,10]

We now apply the SCPRT to the test statistic $B(t^*) = \eta_1^{-1/2} U(t)/D^{1/2}(\tau) \sim N(\theta t^*, t^*)$, which is a Brownian motion in information time $t^* = D(t)/D(\tau)$ on $[0, 1]$, and the drift parameter $\theta = \eta_1^{1/2} \log(\delta) D^{1/2}(\tau)$, where $D(t)$ is defined by Eq. 10 in the section “Sequential Test Statistics.” Suppose k^{th} interim looks are planned at calendar time $t_k^*, k = 1, \dots, K$. Then based on the SCPRT procedure presented above, the lower and upper boundaries for $B(t_k^*)$ at the k^{th} look are given by:

$$\begin{aligned} a_k &= z_{1-\alpha} t_k^* - \{2at_k^*(1 - t_k^*)\}^{1/2}; \\ b_k &= z_{1-\alpha} t_k^* + \{2at_k^*(1 - t_k^*)\}^{1/2} \end{aligned} \quad (20)$$

for $k = 1, \dots, K$, where $t_k^* = D(t_k)/D(\tau)$ is the information time at the k^{th} look at calendar time t_k . The nominal critical p values for testing H_0 are:

$$P_{a_k} = 1 - \Phi(a_k / \sqrt{t_k^*}); \quad P_{b_k} = 1 - \Phi(b_k / \sqrt{t_k^*}) \quad (21)$$

The observed p value at the k^{th} look is:

$$P_{Z(t_k)} = 1 - \Phi(Z(t_k)) \quad (22)$$

The stopping rule for monitoring the trial can be executed by stopping the trial when, for the first time, $P_{Z(t_k)} \geq P_{a_k}$ (accept H_0 and stop for futility) or $P_{Z(t_k)} \leq P_{b_k}$ (reject H_0 and stop for efficacy).

EXAMPLE

Rhabdoid tumors are aggressive pediatric malignancies with a poor prognosis. Over the past years, St. Jude Children’s Research Hospital accrued 14 pediatric patients with recurrent or refractory non-central nervous system (CNS) rhabdoid tumors treated with conventional chemotherapy. The median event-free survival is only about 1 year, where the event is defined as disease relapse or death. All 14 patients had events within about 3 years. The Weibull model was fitted in R to the data, resulting in an estimate (standard error) of the shape parameter $\kappa = 1.37(0.28)$ and median event-free survival time of $m_1 = 0.936$ years, which provides a more satisfactory

model than the exponential model.^[11] Now, suppose that we would like to design a multicenter randomized two-arm trial to assess the effectiveness of the small molecule inhibitor alisertib (treatment 2) versus conventional chemotherapy (treatment 1) for this group of patients. Patients will be randomized with equal allocation to each treatment group and hence $\pi = n_2/n_1 = 1$. The hypotheses of the planned study are $H_0: m_2 \leq m_1$ vs. $H_1: m_2 > m_1$. The investigators would like to detect a half-year increase in the median event-free survival of the alisertib treatment group over that of the conventional chemotherapy group, with 90% power, 5% type I error, and 2 years of follow-up ($t_f = 2$) after the last patient is enrolled in the study. Then, for the alternative hypothesis, $m_2 = m_1 + 0.5 = 1.436$, $\delta = \lambda_1/\lambda_2 = (m_2/m_1)^x = 1.797$, and $\gamma = \log(\delta) = 0.586$. Assume this multicenter trial has the capacity to enroll and treat 20 patients per year. Then, under the assumption of the Weibull model, with uniform entry and no loss to follow-up, the required total accrual time is $t_a = 5.3$ years, calculated by Eq. 16, in which $p_1(\tau)$ and $p_2(\tau)$ are found by Eq. 15 with $\tau = t_a + t_f$. Then, the study duration is $\tau = t_a + t_f = 7.3$ years, and the total sample size is 106 patients (53 per group). Now assuming interim and final looks are planned at calendar times $t_1 = 4$, $t_2 = 5$, and $t_3 = \tau = 7.3$ years, the corresponding information time at each planned interim look t_k can be calculated by $t_k^* = D(t_k)/D(\tau)$, where $D(t) = (p_1^{-1}(t) + \pi^{-1}p_2^{-1}(t))^{-1}$ with:

$$p_j(t) = \frac{1}{t_a} \int_0^{t \wedge t_a} \{1 - S_j(t-u)\} du \quad (23)$$

$S_j(t) = e^{-\log(2)\left(\frac{t}{m_j}\right)^x}$, and $\pi = 1$. By calculation, the corresponding information times are $t_1^* = 0.511$, $t_2^* = 0.706$, and $t_3^* = 1$. Assuming the maximum conditional probability of discordance $\rho = 0.02$, then the boundary coefficient $a = 2.593$ for $K = 3$,^[3] and the maximum probability of discordance is $\rho_{\max} = 0.0043$. That is, under the most unfavorable setting of mean parameter, i.e., the underlying true drift θt^* of Brownian motion $B(t^*)$ is pointing to the cut-off point $z_{1-\alpha}$ of the test at the final stage, on average, for every 1,000 such sequential tests, there would be only 4.3 cases of later reversal of conclusion (significant or futility) at early stopping if the sequential test was not stopped as it should be but continued till the planned end. The lower and upper boundaries calculated from Eq. 20 are $(a_1, a_2, a_3) = (-0.298, 0.124, 1.645)$ and $(b_1, b_2, b_3) = (1.979, 2.199, 1.645)$, respectively. The acceptance and rejection nominal critical significance levels are (0.6615, 0.4415, 0.050) and (0.0028, 0.0044, 0.050), respectively.

CONCLUSION

A multistage group sequential procedure is presented under the Weibull model based on the SCPRT procedure. The advantages of the proposed sequential procedure are: 1) the maximum sample size of the sequential test is the same as that of the reference fixed sample test; and 2) the probability of discordance, or the probability that the conclusion of the sequential test would be reversed if the experiment was not stopped according to the stopping rule but continued to the planned end, can be controlled to an arbitrarily small level.

Abstract

This entry discusses topics related to the z-score, including Gaussian distribution, the standard normal distribution, and the central limit theorem, and provides applications for the z-score.

Keywords: Central limit theorem; Gaussian distribution; Standard normal distribution; Standard score; Standardization.

INTRODUCTION

The z-score is the most commonly used standard score.^[1] It is derived from the standard normal distribution with mean value 0 and standard deviation 1. Therefore, a z-score of an observation represents how far a value deviates from the mean value in terms of standardized or normalized units, more commonly called its standard deviation.^[2] The z-score is commonly used in social science studies, for example, in educational or psychological testing. With a calculated z-score, two different test scores can be compared. However, use of the z-score is not restricted to social studies. Its application can be applied to most areas of scientific study. One such example is a clinical trial for schizophrenia research.^[3]

After a brief introduction, we will discuss topics related to the z-score, including the Gaussian distribution, the standard normal distribution, and the central limit theorem. Finally, the z-score will be formally discussed and its application will be presented.

GAUSSIAN DISTRIBUTION

Another popular name for the Gaussian distribution is the *normal distribution*. It has many other names as well, such as the Laplacian, the Gauss–Laplace or the Laplace–Gauss distribution, and the second law of Laplace.^[2] It is a continuous distribution with a probability density function (pdf) expressed by the formula:

$$f(x) = 1/[\sigma(2\pi)^{1/2}] * e^{-(x-\mu)^2/2\sigma^2}, \quad -\infty \leq x \leq \infty, \quad (1)$$

where μ is the mean and σ is the standard deviation, with $-\infty < \mu < \infty$, and $\sigma > 0$.

The normal distribution is symmetric with its center at the mean that is also the mode and the median. The normal distribution is actually a family of distributions in that

there are an infinite number of normal distributions with a unique correspondence to the (μ, σ) combination. Given a value for the (μ, σ) combination one can obtain the corresponding normal distribution. In other words, the normal distribution is completely characterized and determined by these two parameters, μ and σ . In many standard mathematical statistics text books^[4–6] a random variable X that has a normal distribution with mean μ and standard deviation σ is thus denoted by $N(\mu, \sigma^2)$. We use the notation $X \sim N(\mu, \sigma^2)$ to represent this situation. A general diagram for the normal distribution is presented in Fig. 1.

An important property of the normal distribution is that any linear transformation of a normally distributed random variable is still normally distributed. This property is summarized in the following theorem.

Theorem. If $X \sim N(\mu, \sigma^2)$ and a and b are constants then $a + bX \sim N(a + b\mu, b^2\sigma^2)$.

A reader interested in the proof for this theorem may consult the textbooks mentioned above or any standard mathematical statistics textbooks.

STANDARD NORMAL DISTRIBUTION

If $X \sim N(\mu, \sigma^2)$, then when $\mu = 0$ and $\sigma = 1$, the corresponding normal distribution is called the *standard normal distribution*, denoted by $N(0, 1)$. The pdf, $f(x)$, of a standard normal distribution is given by the following expression,

$$f(x) = 1/(2\pi)^{1/2} * e^{-x^2/2}, \quad -\infty \leq x \leq \infty, \quad (2)$$

and its corresponding cumulative distribution function (cdf), $F(x)$, is given by

$$F(x) = \frac{1}{2\pi^{1/2}} \int_{-\infty}^x e^{-y^2/2} dy; \quad (3)$$

this is often denoted by $\Phi(x)$.

Fig. 1 Normal distribution

Some of the basic properties of $f(x)$ can be found in standard statistics handbook,^[7] for example:

$$f(-x) = f(x) \quad \text{and} \quad F(-x) = 1 - F(x). \quad (4)$$

$f'(x)$ is the first derivative of $f(x)$ with respect to x :

$$f' = \frac{-x}{2\pi^{1/2}} e^{-x^2/2} = -xf(x). \quad (5)$$

$f''(x)$ is the second derivative of $f(x)$ with respect to x :

$$f'' = \frac{x^2 - 1}{2\pi^{1/2}} e^{-x^2/2} = x^2 - 1f(x). \quad (6)$$

$f'''(x)$ is the third derivative of $f(x)$ with respect to x :

$$f''' = \frac{3x - x^3}{2\pi^{1/2}} e^{-x^2/2} = (3x - x^3)f(x). \quad (7)$$

$f^{iv}(x)$ is the fourth derivative of $f(x)$ with respect to x :

$$f^{iv} = \frac{x^4 - 6x^2 + 3}{2\pi^{1/2}} e^{-x^2/2} = (x^4 - 6x^2 + 3)f(x). \quad (8)$$

A table that contains all of the above related functions of $f(x)$ can also be found in the reference work edited by Beyer.^[7] Other forms of the standard normal tables can be found in the books by Conover^[8] and Panago.^[9]

The standard normal distribution has many applications because of the famous central limit theorem that can be found in most standard mathematical statistics books.^[4-6]

Central Limit Theorem. If $X_1, X_2, \dots, X_n$ is a random sample drawn from a distribution that has mean μ and positive variance σ^2 . Then the random variable $Y_n = n^{1/2}(\bar{X} - \mu)/\sigma$ has a limiting distribution, as n approaches infinity, that is normal with mean 0 and variance 1. Here, $\bar{X}$ is the sample mean of the random sample, i.e., $\bar{X} = \sum_{i=1,n} X_i/n$.

Simply stated in mathematical terms, the central limit theorem asserts that the random variable Y_n defined above converges to z , where $z \sim N(0, 1)$, in distribution; or equivalently, the sample mean, $\bar{X}$, converges to the population mean, μ , in distribution.

There are many applications to the central limit theorem because the population distribution for the random variable X is not specified. When random variables have a finite mean and a positive variance, then the central limit theorem applies. For example, if X has a Bernoulli distribution with parameter p , then the central limit theorem becomes the normal approximation to the binomial distribution that can be found in many standard mathematical statistics textbooks.

Another application of the standard normal distribution is for Monte Carlo studies where the standard normal distribution is used to generate any arbitrary normally distributed random variable with a specified mean μ and variance σ^2 . In SAS® programming language^[10] there is a random number generator function, RANNOR(seed), and a corresponding CALL routine, CALL RANNOR(seed, x), that can generate random numbers from a standard normal distribution.

Using the theorem presented in Section II with $\mu = 0$ and $\sigma = 1$, and selecting $a = \mu$ and $b = \sigma$ then that theorem becomes the following:

Lemma. If $X \sim N(0, 1)$ then $\mu + \sigma X \sim N(\mu, \sigma^2)$.

One can easily generate a set of random samples that is normally distributed with mean μ and variance σ^2 using this lemma and the random number generator function RANNOR(seed). Such an example has been illustrated in Fan et al.^[11]

DEFINITION OF Z-SCORE

As mentioned earlier, the z -score describes how far a sample value has deviated from its mean value in terms of its standard deviation units. A formal definition of the z -score, presented by Pagano,^[9] states that:

A z -score is a transformed score that designates how many standard deviation units the corresponding raw score is above or below the mean.

In terms of the standard normal distribution, the z -score is indeed the abscissa under the standard normal curve. Knowing the z -score for a sample value, one can use the standard normal table (e.g., Table A from Pagano^[9]) to tell the relative standing, in terms of percentage, of this value of the whole sample. For example, a z -score of 1.645 (using linear interpolations) means that this value is in the 95th percentile of the whole sample or that 95% of the values in this sample are less than or equal to this value. To obtain the z -score, say z , of a sample value, say x , from a normally distributed random sample with mean μ and variance σ^2 ,

simply subtract the mean value from x and then divide by the standard deviation. That is,

$$z = (x - \mu) / \sigma. \quad (9)$$

The process of using Equation 9 to find the z -score of a sample value in a normally distributed random sample is often referred to as the process of standardization. This process allows two different values, coming from different normal populations, to be compared to each other, including those with different units for each distribution. This is accomplished using the standard normal table and their corresponding z -scores obtained in this manner. To illustrate, consider the following example. You want to compare your height with your weight to see if you are relatively taller or relatively heavier than others in a particular group. Assume that your height and weight measurements are 76 in and 180 lb, respectively, that the height measurement in that particular group follows a normal distribution with mean = 68 in, and SD = 4 in, and that the weight measurement in that group follows another normal distribution with mean = 160 lb, and SD = 20 lb. Given this information, we can easily calculate the z -scores for both your height and weight measurements using Eq. 9. The z -score for your height is $(76-68)/4 = 2$, and the z -score for your weight is $(180-160)/20 = 1$. Therefore, using the standard normal table, your height ranks 97.72% ($z = 2$) relative to that particular group, although your weight only ranks 84.13% ($z = 1$) relative to the same group. Your height has a much higher ranking than your weight compared to that particular group. Consequently, you know you are much taller and heavier than that group's average.

APPLICATIONS

The application of a z -score is many fold. Because the z -score is tightly related to the standard normal distribution, any application of the latter can be seen as an application of the former. For example, in elementary statistical textbooks the hypothesis testing procedure using the normal distribution (sometimes referred to as the z -test) is an application of the standard normal distribution. The test statistic, z , in such a procedure is indeed a z -score. Therefore, the hypothesis testing procedure is also an application of the z -score. To extend this logic, any transformation that results in a standard normal distribution as the limiting distribution may be viewed as an application of the z -score. This is because such a transformation eventually relies on the z -score to infer whether it is for hypothesis testing or for an estimation of the confidence limits or bounds.

We have previously illustrated by example how to use the z -score to compare two different things with different units. By transforming different item scores into z -scores, one can easily compare these item scores through their z -scores. This procedure of standardization allows you to

“compare apples with oranges.” Without the use of z -scores such a comparison is not possible.

The central limit theorem mentioned earlier is a powerful tool that can transform a random variable, derived from a random sample, so that it has a limiting standard normal distribution. Therefore, as mentioned above, this will also be an application of the z -score.

Also mentioned in the previous section is use of the standard normal distribution to generate a random sample from any normal distribution in Monte Carlo studies. In a broad sense, this can also be treated as an application of the z -score.

In an example from a clinical trial that uses the z -score as a way of evaluating efficacy variables, Keefe et al.^[3] studied the effect of BACS (the Brief Assessment of Cognition in Schizophrenia) in patients with schizophrenia. The BACS is a measurement that consists of six domains for cognitive function: verbal memory, working memory, motor speed, attention, executive functions, and verbal fluency. It is found to be fully portable, and is designed to be easily administered by a variety of testers, including nurse clinicians, psychiatrists, neurologists, social workers, and other mental health workers. There are two groups in this study: treatment group and healthy control group. The allocation of patients in these two groups is 3:1 such that with every three patients in the treatment group there will be 1 healthy subject in the control group. The total number of subjects is 200, with 150 in the treatment group and 50 in the control group.

Data analysis for this study has a primary measure from each test (domain) of the BACS. Each measure was standardized by creating z -scores whereby, for test session 1, the healthy control mean was set to 0 and standard deviation set to 1. A composite score was calculated by averaging all of the six standard primary measures from the BACS, and then calculating a z -score of the composite. The relative sensitivity of the composite scores derived from the standard battery and the BACS was determined by comparing each of their between-group differences with t -tests. Other details of this study can be found in Keefe et al.^[3]

This is an example, published in the literature, that used the z -score of the efficacy variable as the primary measurement for data analysis and it serves as a good application of the z -score.

V

Vaccine Adverse Event Reporting System (VAERS), 638
 vaccine efficacy, 237, 629
 based on ratio of two binomial proportions, 630
 based on ratio of two rates, 630–631
 estimates, 631

sample size and power calculation for
 vaccine efficacy trials, 632
 trials to estimate relative, 631
 vaccine immunogenicity analysis
 different types of, 634
 bridging study, 635
 combination/multivalent vaccine study, 635
 consistency lots study, 634–635
 dose response immunogenicity study, 634
 immunologic persistence study, 635
 superiority immunogenicity study, 634
 general approaches to, 632
 geometric mean titers, approaches for analyzing, 633–634
 immune response rates, approaches for analyzing, 633
 immunogenicity endpoints, 632
 noninferiority/equivalence margins, considerations for, 634
 sample size and power considerations for, 636
 bridging study, 636
 combination/multivalent vaccine study, 637
 consistency lot study, 636
 vaccine licensure, regulatory process for, 629
 vaccines, 234
 economic evaluation of, 640–641
 immune surrogate and correlate of protection for, 640
 issues in, 237–240
 vaccine safety, assessing, 637–639
 vaccine trials, additional statistical issues for analyzing, 639
 analyses with stratification variables, 639
 intention-to-treat or per-protocol analysis, 639
 interim analyses, 639
 missing/coarse data and loss to follow-up, 639
 Vaginal Infections and Prematurity (VIP) Study, 1628
 vague conjugate priors, 171
 validation, defined, 1101, 1802
 validation test, 1122, 1123
 validity, 1174
 of bootstrap, 343, 345, 346
 concurrent, 1175
 construct, 1175–1176
 Valtropin®, 309
 value tree, 481
 variable acceptance sampling plans, 1
 variance-balanced design, 2210
 variance-component method/model, 1059, 1061
 variance components
 extension of MLS method to difference of, 1428–1430
 extension of MLS method to ratio of, 1430
 process validation, 1805
 variance-covariance matrix, 997, 1316, 2148
 variance estimation, 344, 1232
 statistical inference, 1130
 variance inflation factors (VIFs), 648, 1444, 1448

variation, comparing intrasubject coefficients of, 489
 Vascular Quality Initiative, 1791
 Venclexta® (venetoclax), 1648
 ventricular depolarization, 2206, 2207
 ventricular fibrillation, 2206
 ventricular myocytes, 2206
 ventricular premature contractions (VPC), 961
 Veterans Administration lung cancer trial, 559
 Veterans' Health Administration health performance monitoring study, 1414
 visual analogue scales (VAS), 1121
 visualization, 481
 bar graphs, 482
 effects table, 481
 forest plots, 482
 tree diagrams, 481–482
 volume under the ROC surface (VUS), 1608
 Vysis CII Fish Probe kit, 1648

W
